Fundamental Repair of Partial and Complete Lacerations of the Perineum.—Dr. Albert Goldsphon of Chicago stated that mistaken conceptions about the anatomy of the female perineum had caused errors in technique of operations for lacerations of it; and that these mistakes had not yet been wholly eliminated. The profession was now pretty well agreed that the formerly standard operations of Hegar, Martin, Emmett, etc., and their many modifications were merely vaginal resections of variable depth and extent, without restoration or improvement of real bearing structures beneath them. That a reunion of the bilaterally descending portions of the levator ani with its fasciae, near the median line, between the rectum and the vagina, was the chief desideratum, was generally admitted and striven for; but that there was still much difference of opinion about the exact location and accessibility of the levator ani, and that more superficial structures were often mistaken for it. Because of its laterally receded position normally within the pelvis beyond the narrower introitus, the levator would not step out toward the median line into plain view within the lumen of the wound in any dissection; and that all who represented it thus in their illustrations were clearly mistaking the urogenital diaphragm (triangular ligament) for it which would present itself in such a manner. The anatomy of the female perineum was best studied as composed of three strata, the component parts of each of which were illustrated by exact drawings made of sections and dissections of specially prepared female pelves that were made by Edward Martin and by Biepmann, under the supervision of Waldeyer. All pursestring or figure of eight sutures that engaged the levator structures and also some structures in the outer portion of the wound or the skin, were wrong in principle and poor in effort, that efficient union of the most important parts (levator and urogenital diaphragm) could only be secured by direct apposition without any intervening tissues, by means of direct and transversely placed buried sutures. He described and illustrated the technic of operations for both complete and incomplete lacerations of the perineum.

Median Episiotomy in Primiparous Labors.—Dr. James A. Harrar of New York City said that median episiotomy was a simple operation of valuable assistance in preventing relaxation of the pelvic floor after labor, in shortening the second stage of labor and in reducing the number of low forceps operations. It was better than the lateral incision, as it separated chiefly muscles in the raphe rather than in their continuity. Median episiotomy wounds healed better than lateral ones or spontaneous lacerations.

President's Address: Incidence of Malignancy in Gall-Bladder Disease.—Dr. John F. Erdmann of New York City said that he began with the first half of this year and recorded 9 carcinomatous gall-bladders, and so forth, of 68 operations upon the gall-bladder, occurring in an operative list of 502 patients. The second half of 1918 presented 3 malignancies in a series of 63 operations on the gall-bladder in an operating total of 491 patients. The second half of 1918 presented but two malignancies of this viscus in 47 operations out of a series of 474 major operations, The last half of 1917 gave but one malignancy in 47 gall-bladder operations out of a general operative list of 506. These figures and statements showed in the main the remarkable occurrence of malignancies in the early months of this year and went to prove his contention that the first portion of this year must be considered but a coincidence in malignancies. A summary of these cases gave the following for the past two years, feeling that this period of time would be ample for a relatively satisfactory conclusion on the part of an individual operator: June 15, 1917, to June 15, 1919, patients operated upon, 1903. Operated upon for cholecystitis, 224; malignancies found in the gall-bladder, 15, making a percentage of 6.7 of all gall-bladder operated cases, and 0.8 per cent. gall-bladder malignancies, found in his entire operative work during these twenty-four months. He wished to emphasize the fact that there were a number (13) of operative cases of general abdominal carcinomatosis, in which the primary focus could not be positively demonstrated, but in the majority of these the point of greatest involvement was in the neighborhood of the gall-bladder. The stomach and immediate structures were positively not the source of origin. In this number of 1903 patients operated upon, malignancies of all kinds, excluding the lip epitheliomata, were found 285 times. Recalling that 15 of the 285 malignancies were of the gall-bladder, the occurrence of gall-bladder malignancies to the whole number of malignancies was about 6 per cent. The malignancies positively specified in the collection were: Gall-bladder, 15; stomach, 43; breast, 66; cecum, 12; colon and sigmoid, 28; rectum and rectosigmoid, 29; not specifically classified, 79. This number, 79, included uterus, kidney, larynx, tongue, liver, thyroid, etc. In all of the patients with carcinoma of the gall-bladder recorded in this communication, stones were found in the gall-bladder. It would seem, therefore, that the presence of gall-stones or biliary sand was a provocative factor in the production of malignancy. Such being a fact, or even a hypothesis, the early elimination of such agents was advisable. The operative treatment of this disease bore rather weighty consideration. He had found personally that interference with the gall-bladder, unless a complete cholecystectomy could be done, was prone to be followed by a rapid death. By operative interference he wished to convey the idea of removing the stones since they were erroneously felt to be the entire source of pain, or by doing an ostomy or ectomy, if the growth began to be or was established in the cystic fissure, or if any suspicious metastases were in surrounding viscera. A satisfactory ectomy could be found in certain fundus and body of the gall-bladder involvements. These were the cases found, as a rule, as accidentals to the operation for a cholecystitis. A close review of the statistics herewith presented would justify the advice that an established diagnosis of cholecystitis predicted the possibility of occurrence of cancer, almost double that of the possibility of a mortality in case of operation.

Inversion of the Uterus.—Dr. H. Wellington Yates of Detroit stated that there were three varieties of inversion of the uterus according to the degree of displacement. First, consisting in a simple dipping in or a cupping of the fundus. 2. Where the fundus descended below the os uteri. 3. Consisting in a complete descensus through the os and vagina with the whole fundus visible outside the vulva. This latter condition might be so exaggerated that the vagina was partly inverted and the uterus dragging down the tubes and ovaries, making a complete uterine inversion with prolapse. Two or three factors were necessary for the production of this phenomenon—pressure from above, traction from below, together with a localized atony or thinness of the uterine walls. Some of the exciting causes were the implantation of the placenta at the fundus, submucous fibroids which had become pedunculated during pregnancy and manual extraction of the placenta. Exceptional instances of spontaneous inversion had occurred as a result of intraabdominal pressure; other causes were those of the mother giving birth while in a standing position; short umbilical cord or the cord twisted about the child's neck or body; hard coughing, sneezing, etc., at the end of long wearisome labors. The two most important causes recorded in the order of their frequency had purposely been placed last in this series: (1) too early adoption of the Crede method, together with its improper use; (2) traction upon the cord as a means for the detachment of the placenta or a combination of the two—traction from below and compression from above simultaneously. The greater majority of inversions were due to faulty technic. As regards prophylaxis, it could not be too strongly emphasized, first, that the cord should not be dragged down; second, that Crede's method should not be injudiciously employed; third, that in no instance should the fundus uteri be so pressed down that indentation was made upon it; fourth, that Crede's method should not be employed except when the uterus was in contraction. This last in his opinion was highly important; fifth, the obstetrician should remain with the patient until a firm uterine retraction had been established. The more recent the inversion, the more surely and safely it could be reduced.

Cesarean Section: Its Indications and Technique.—Dr. Arthur J. Skeel of Cleveland, Ohio, stated that 48 of the cases were operated in his home hospital where he could control the technique. Five of them were in other hospitals where the technique was not amenable to his direction. There were no deaths and no infected incisions among the 48 cases in his own operating room. There was one maternal death and one sloughing wound among the 5 cases operated outside. Whether the difference was due to operating room technique was, of course, impossible to say. There could be no doubt, however, that in many small hospitals, without a well organized surgical staff, the technique was so poor that one must question his right to subject his patient to this uncertain factor. His preference was to operate after labor had started. The cervical dilation thus secured permitted freer drainage, less operative pain, less vigorous uterine contraction, with less movement in the uterine wound. The abdomen was shaved, scrubbed with green soap and sterile water, dried, scrubbed with 95 per cent. alcohol, scrubbed with Harrington's solution, scrubbed with alcohol. The incision had been either high or medium. In the later cases mid-line incision, with the navel at its middle, had been used. He did not know of any good surgical reason why the navel should constitute a landmark below which the incision should be extended. The umbilicus was usually excised to secure a more favorable suture line. The true extraperitoneal operation might have some advantages, but from the literature and the few cases the writer had seen there was so much chance of tearing the peritoneum that it seemed to offer little certainty of not entering the cavity. The low transperitoneal operation so much lauded as protecting the peritoneal cavity by suturing was a true intraperitoneal operation so far as postoperative peritonitis was concerned. Peritonitis following cesarean section was acknowledged to be wound infection. At postmortem and on opening for drainage the infection could be distinctly traced from the interior of the uterine cavity through the incision and along the suture lines. Careful stitching of the abdominal to the uterine peritoneum, overlapping of the layers of peritoneum, making the abdominal incision and the

uterine incision at right angles to each other, all left the same condition when the operation was completed. When a patient had had one section for disproportion, the writer believed that the abdominal route should be chosen for the next delivery. If the first section was for any cause except disproportion, the case should be in the hospital with competent supervision, and the method of delivery selected as circumstances might indicate. The repeated section was by no means so simple an operation as the first one. Adhesions were the rule. Of the six cases of this series, adhesions were numerous in 5 and absent in only one. The densest adhesions of omentum and gut were invariably at the upper end of the scar. The incision for the second operation was best made lower down than the first and lateral to it, going through the peritoneum first at the lower angle. In this manner one usually entered the free peritoneal cavity at once and could deal with adhesions advantageously. It had been the writer's practice to free the uterus thoroughly, but to leave the adhesions to the abdominal wall alone, if they presented no special reason for interference. In five of these six cases the uterine scar was firm and discernible with difficulty. Often it could be recognized only during a contraction.

Prophylaxis of Gestation.—Dr. Asa B. Davis of New York City said that prophylaxis of pregnancy (prenatal care) meant a supervision of the pregnant woman throughout the whole nine months of gestation. It meant the giving of instruction to her as to her mode of life, clothing, her occupation, exercise, sleep, diet, the attention to hygienic care of her body, bathing, the avoidance of constipation, etc. She should be the subject of regular monthly observations during the first six and bi-monthly during the remaining three months of pregnancy and as much oftener as the nature of her case required. At such times, her urine should be examined and her blood pressure taken. Early in pregnancy there should be a thorough physical examination which should include careful external and internal pelvimetry. She should be instructed to report promptly anything which she considered to be abnormal and bring the questions which arose and annoyed and perplexed her, for answer. The aim should be to anticipate and avert complications. If they did arise, to detect them early, while they were yet relatively unimportant and treat them at this stage. Disturbances of vision should call for prompt ophthalmoscopic examination. Only by this were we able to distinguish between toxemia of late pregnancy and the exacerbation of chronic nephritis during pregnancy. In the former, structural changes in the eyes were rarely detected and the symptoms were transitory if the toxemia was removed. In the latter structural eye changes were the rule and they might demand prompt interruption of pregnancy in order to save the eyesight. The relations between accoucheur and patient, in so far as the reproductive process was concerned, should be that of mutual understanding and confidence in order to secure the necessary cooperation. This placed obligations upon both parties, upon the former, that he should be competent and honest; alert in his interest and well sustained watchful care; careful and thorough in his investigations. If absorption and sterilization were to be done, the most satisfactory way was to empty the uterus by abdominal hysterotomy and resect a portion of the tubes from the uterus outward, ligate the distal end and suture peritoneum over the cut ends. But we needed more light and cooperation upon this subject from specialists who were treating tuberculosis. The decision to bring about this great change in a woman's life should not rest upon, it might be, the fiat of a hurried physician working in a dispensary for tuberculosis patients and acquainted with but one side of the question.

My Experience With Cases of Version During the Past Year, September, 1918, to September, 1919.—Dr. Irving White Potter of Buffalo, New York, stated that since the meeting of last year he had personally delivered 1010 women, 450 of whom were primiparæ and 560 multiparæ. Of this number there were fourteen pairs of twins. For various conditions version was performed 680 times, 300 in primiparæ, 380 in multiparæ. For delayed rotation of the occiput from either the right or left posterior position, there were 545 cases. There were 4 face presentations with the chin either anterior or posterior. Prolapsed cord furnished 9 cases. Arm presenting furnished 3 cases, which would have led to a neglected shoulder presentation if not attended to. Placenta previa marginalis, 8 cases. There were 42 cases of vertex presentation that were delivered by forceps because the head could not be raised up through the pelvis, owing to too firm uterine contractions. Eighty-eight cases were seen in consulation with physicians; 11 cases seen with midwives. There were 43 stillborn children in the 1010 deliveries, and of this number 680 were delivered by version, representing a total fetal mortality of 43 cases. Instruments were applied to the aftercoming head twice, and he believed the more familiar we were with the proper method of version, the fewer times we would find it necessary to apply the forceps to the aftercoming head. There was no maternal mortality, and the maternal morbidity was no greater than in other methods of delivery. There were no lacerations of the maternal parts that required anything more than simple repair, and he meant by that a slight tear up to but not through the muscle. He described in detail the steps necessary to a succesful version.

The Cystic Ovary.—Dr. Francis Reder of St. Louis said that although the so-called cystic degeneration of the ovaries according to later research work was looked upon for the most part as a physiological process, the fact must not be lost sight of that also a pathological condition was at work which exerted a destructive potency upon the parenchyma of the organ, thus impairing its functional efficiency. A cystic ovary was usually discovered in the course of an abdominal operation. Resection of the cystic area and puncture of the scattered cysts alone rarely cured the condition. Proper suspension of the organ to reestablish and augment its vascular supply, together with a well regulated hygienic management of the patient, might eventually effect a cure. Without an abnormal position of the uterus, be it a retrodeviation or a descensus due to ligamentous relaxation in which the uterus might be anteverted, there was seldom a prolapsus of the ovary; without a prolapsus of the ovary there was no abnormal hyperemia, and without an abnormal hyperemia there was rarely a cystic ovary.

Chronic Oophoritis and the Cystic Ovary.—Dr. Otto H. Schwarz of St. Louis stated that chronic oöphoritis necessarily meant a chronic inflammatory process in the ovary, and it should embrace only such lesions as could be definitely attributed to the effects of inflammation. It was almost always a secondary disease, secondary usually to an infection of the tubes, and therefore most frequently of gonorrheal origin; infection from a puerperal origin was also frequent. In the description of chronic oöphoritis most authorities agreed that the periovarian adhesions with sclerotic changes in the ovary were most characteristic. A series of 80 cases were studied in which one or both ovaries were removed at operation. With few exceptions, the removal of the ovaries was of a secondary nature; they were either diseased themselves in association with more important pelvic lesions, or were removed in the course of a hysterectomy. When the ovary was removed for a new growth, it was not included in the series. In going over these specimens a diagnosis of chronic oöphoritis was made in 24 cases; 16 of these cases were operated on for chronic adnexal inflammatory masses; in these cases, without an exception, there was a very marked inflammatory process in the tubes. The ovaries were densely adherent to the tube, in some instances it was very difficult to recognize them, so intimately were they connected. The ovaries were enlarged in 10 of these cases; usually the enlargement was rather moderate; there were several instances the size of hens' eggs, but no larger. On six occasions they were of normal size; some perhaps slightly smaller. Microscopic examination of the tube in each of these showed a marked chronic salpingitis. In the 8 remaining cases uterine myomata were present. These were for the most part rather small myomata. In two of these cases the ovaries were markedly adherent to a chronically inflamed tube; in the others there was only slight evidence of pelvic inflammation, but the tubes on microscopic section, with

one exception, showed a definite chronic inflammation. The one case which showed no tubal inflammation had a definite chronic inflammatory process in the endometrium and in the uterine wall. Cystic degeneration of the ovary was found most frequently in cases of noninflammatory nature. In a considerable majority of cases, there were no changes in the ovary which could be attributed to inflammation. Small round cell infiltration, one of the usual findings in chronic inflammation, was not in evidence.

Removal of Large Cyst of Right Parovarium, Followed by Cesarean Section; Fibroma of Round Ligament.—Dr. ARTHUR T. JONES of Providence, Rhode Island, stated that in the first case, a median incision was made from the pubes to the ensiform, and the tumor, which was an enormous cyst of the right ovary, was removed without difficulty. The appendix was found enlarged and was removed. The incision was closed in layers by the usual method. The tumor contained 43 pints of fluid and with sac weighed fifty pounds. Patient made a good and uninterrupted recovery. In the second case a laparotomy was done through a median incision; a large cyst of the right parovarium was delivered and removed. The uterus was then incised and a live child delivered, placenta removed, and the uterus closed in two layers. Abdominal incision was closed in layers. Patient made an uninterrupted recovery. In case 3 the tumor was found to be hard and fibrous, attached to the distal end of the round ligament. The latter was dissected along to the internal ring. The peritoneum was opened at the internal ring, uterus palpated, and found to contain small fibroids on the posterior wall low down near the cervix. Both appendages were found adherent to the underside of the broad ligaments, the ovaries were sclerotic, and tumor with a portion of the round ligament was cut away. The peritoneum at the internal ring was closed and also the internal ring closed around the round ligament, the latter stitched between the edges of the external oblique as in the Alexander operation. The incision was closed. Patient made an uneventful recovery.

Two Early Cases of Adenomyoma.—Dr. OTTO H. SCHWARZ of St. Louis stated that the first case was an adenomyoma arising in the rectovaginal septum; the other a case of adenomyoma of the ovary. The tumor of the rectovaginal septum was of particular importance because it represented a new growth in its earliest stage and it brought up the possibility of recognizing this type of tumor clinically at this early period. The adenomyoma of the ovary was a most unusual tumor, as only a few well described cases had been reported in the literature. These tumors had been thoroughly studied by Lockyer of England, and Cullen of this country. After a thorough search of the literature Lockyer found 47 cases reported in which were included 4 of Cullen's cases. Adenomyomata of the rectovaginal septum usually started just behind the cervix and on bimanual examination one could feel in this region a small, somewhat movable, nodule scarcely over a centimeter in diameter. The rectal mucosa could at this stage be readily made to slide over the tumor. The clinical findings in his case fulfilled exactly these conditions.

Protective Changes in the Oviduct.—Dr. JAMES E. DAVIS of Detroit stated that the proximal ostium was a short transition from the uterus to the tubal structure. Its very efficient long valve constructed of strong muscle fibers and primary folds was an interesting contrast with the ostium abdominale. It was a mistake to understand that this ostium was a valve consisting of a few narrow muscle fibers. Transsections of the uterine cornu and first portions of the tube proved the extent of this ostium. The outward, backward. downward, and inward position of the tube, as found in the great majority of pathologic processes, if not associated with tubal pregnancy, was signally beneficial for protection. The first essential of tissue repair, rest, was obtained by splinting against the ovary and uterus. The abdominal ostium in this manner became intimately adherent to a peritoneal surface. This position facilitated a decreased blood supply and atrophic changes. Thirty cases, illustrating 23 types, were reported of morphological and histological tubal changes.

The Treatment of Vaginal Discharge.—Dr. GEORGE F. CHANDLER of Kingston, New York, advocated the principle of treating ordinary discharges of the vagina by a so-called dry method. Six treatments were given. The first three treatments consisted of swabbing the cervical canal with pure carbolic acid and painting the entire vaginal mucous membrane with a weak solution of iodin, after which the vagina was packed with dry sterile gauze in sufficient quantities to straighten out all the folds. The last three treatments consisted of the application of a powder made of equal parts of stearate of zinc, starch, and boracic acid, and packing the vagina with sterile gauze. The advantages claimed were that this treatment cured more quickly than any other method.

The Buried Loop Operation for Shortening the Round Ligaments.—Dr. JOHN NORVAL BELL of Detroit said that he had devised the following operation: The usual median incision having been made, the necessary attention given the pelvic pathology, the round ligaments were then brought out through a perforation of the abdominal wall as in the Gilliam operation. A strip of fascia from one-half to one inch in width was now cut transversely and dissected from the rectus. The fascial flap was drawn through the loop of ligament, replaced in its original position, and sutured there. The loop of the ligament was buried beneath the fascia and could not escape to slide back into the abdominal cavity. Not infrequently the loop of ligament on one side was shorter than the other. Where such a condition existed the fascial flap could be cut narrower. In other words, the flap could be cut to accommodate the length of the loop. The freshly cut edges of the fascia lying in apposition and union should be firm and prompt. All necessary plastic work should be done in the perineum and vagina.

The Varieties and Treatment of Dysmenorrhea.—Dr. J. HENRY CARSTENS of Detroit stated that dysmenorrhea was due to obstruction, to abnormal conditions of the membrane, to inflammation of the tubes, to pelvic adhesions, and to an aberrant action of one or more of the ductless glands. The treatment should consist of dilatation and the use of the stem pessary to make it permanent, to abdominal section and removal of the tubes, or the restoration of them, and the breaking up of adhesions. The use of preparations of ductless glands, as indicated.

Clinical Facts Concerning the Stem Pessary.—Dr. THURSTON S. WELTON of Brooklyn, N. Y., drew the following conclusions: "In the absence of infection a stem pessary may be introduced, provided the patient refrains from sexual relations while the stem is in place, puts herself under constant observation, and reports to her physician at the first early indication of trouble. We do not condemn the stem as an unnecessary instrument. It gives excellent results in properly selected cases of dysmenorrhea; otherwise our results with the stem have been negative. A stem can be the starting point, the exciting cause, of pathology, such pathology either limited to the cervical tissues or invading the deeper structures and ascending and involving the field higher up." From which conclusions he made the plea that the use of the stem pessary, often held lightly and without appreciation of its contraindications and dangers, be discouraged in the hands of the casual gynecologist ignorant of its menace to the welfare and health of the patient.

A Study of Certain Bands in the Right Upper Abdominal Quadrant, Illustrated by Cases.—Commander WILLIAM SEAMAN BAINBRIDGE, M.C., U. S. Navy, of New York City, stated that his object was to draw attention, first, to some points which had proved of practical value to him when operating upon the abdominal viscera; second, to report in brief some selected illustrative cases. (1) The prone position often failed to give the surgeon an exact conception of the conditions present when the abdomen was opened. Early bands and adhesions were often overlooked or their importance not realized. The reverse Trendelenburg would be of aid in arriving at an exact diagnosis. However, this frequently was not sufficient. We must put traction downward on the hollow organs so as to picture what would be the relations if the erect posture were assumed. (2) It was only after the anatomist placed the body erect, froze it in that position and made sec-

tions, that the exact anatomy of the body cavities and their organs were determined. The röntgenologist early realized that much could be learned by the examination in the upright position. Would not a few dissections made by the abdominal surgeon, with the body upright, be of great value in preparing him for his work? He had found it so himself. (3) Many a small band of adhesions when seen in time, and its significance understood, would, if treated adequately, prevent more serious conditions. (4) Breaking up of adhesions was an unfortunate term. In very bad cases that might be all one could do; literally tear these bands and hope that chance would bring those which inevitably reformed in places where they would not do as much harm as before. Success sometimes followed such a course, but more often failure. By carefully dividing bands transversely and suturing longitudinally, by flaps of peritoneum or of omentum or skin grafts, many a case of distressing adhesions could be cured. (5) Early adequate attention to bands and adhesions in the right upper abdominal quadrant often made such operations as cholecystotomy, cholecystectomy and gastroenterostomy unnecessary. (6) Might it not be possible that by a just estimate of the mechanics of the abdomen and careful attention to the lessons learned, we might better order our lives from the beginning and so often prevent the formation of bands and adhesions, thus obviating their serious sequellæ?

Short Incisions Versus Long Incisions.—Dr. ROBERT T. MORRIS of New York City said that in operative work we were to use as short incisions and as little manipulation of the tissues as might be safest for our purposes. The operator who was not very expert required a great deal of room for his work. He must work by sight and through an incision perhaps several inches in length; whereas a more expert operator could operate through an incision one or two or three inches in length. In other words, a very short incision was the one which on general principles gave the smallest proportion of toxic substance and the smallest degree of destructive nerve impulse. On the other hand, what he called the mackerel incision, such as one learned in the fish-shop, was the one which gave the greatest degree of shock. Therefore, it was very desirable to use the shortest incision possible for one's work through which he might work safely and comfortably in the interest of the patient.

Syphilis as a Cause of Delayed Healing in the Non-infected Abdominal Incision.—Dr. WILLIAM EDGAR DARNALL of Atlantic City stated that in his own experience, which covered an active service of nearly twenty years, he could find but three cases among hundreds of abdominal incisions. Two of his cases occurred in patients with incisions below the umbilicus and one above. The first case was in his early experience, a ward case, a negress, on whom he did a subtotal hysterectomy for large fibroids. The case was a perfectly clean one. There was no indication after the operation of any infection of the incision either locally or constitutionally. He thought she was making a beautiful recovery until the removal on the tenth day of the silkworm sutures from the skin. Then the whole wound fell wide open, peritoneum and all, and one could look with unobstructed view clear to the bottom of Douglas' cul-de-sac. She became infected and died. This was before the discovery of the Wassermann reaction, but the almost universal prevalence of syphilis among the southern negro at least placed her under suspicion. The second case occurred in 1913 in a husky Italian on whom he did a cholecystostomy. The incision was made through the right rectus muscle. Five days after the operation the incision showed no healing and no infection and the intestines were protruding. He was taken to the operating room and sewed up again and fed actively on iodides with the result that his incision healed perfectly. His Wassermann was positive. The third case occurred in a patient on whom he did a Wertheim operation for carcinoma of the cervix. The other two cases were strong and robust. This one was of lowered vitality, although the cancer had not progressed extensively. These three cases were not enough to base conclusions upon, but two were definitely syphilitic and the other probably so. This evidence was enough to suggest syphilis as one of the causes, at least, of delayed healing in the abdominal incisions.

Abscess of the Liver.—Dr. JOHN W. KEEFE of Providence, Rhode Island, stated that abscess of the liver was always the consequence of infection. The infecting agents might reach the liver directly, as when in consequence of traumatism bacteria were introduced directly into the liver. Infection might be carried by the blood stream, through the portal vein, hepatic artery and hepatic veins. Without doubt, this was the usual route of entrance of the infective organisms, although they might gain access to the liver by way of the lymphatics. There might be extension of disease of adjacent organs, namely, the gall-bladder. Ulcerative endocarditis might be the primary cause. Appendicitis also might be the forerunner of liver abscess, the infection then took place through the circulation following thrombophlebitis or by retrocecal extension. By far the most frequent cause of abscess of the liver was dysentery, especially amebic dysentery. This form might be accompanied by pylephlebitis. It was apt to be found in subjects fond of alcohol, especially gin, and those who led an irregular life with exposure to the elements, poorly housed and poorly fed. Multiple abscesses of the liver of pyemic origin and suppurative pylephlebitis were practically always fatal. The traumatic abscesses, those following dysentery, appendicitis, and those due to extension from a purulent gall-bladder might be amenable to surgical intervention. Emetine hydrochloride or hydrobromide, ½ to ⅓ grain, administered subcutaneously, was of value when the *Ameba histolytica* was found. The probable location of the abscess must determine the point of attack. An anterior incision might be the most desirable in certain cases; but in incision in the eleventh interspace mid-axillary line was one of choice in the large percentage of cases. The pleural cavity and diaphragm must be traversed before reaching the liver. The capsule of the liver should be incised and a blunt-pointed clamp inserted through the liver substance into the abscess cavity; the clamp should then be opened and withdrawn in this position, thus enlarging the original point of entrance. We should avoid the use of the trocar and cannula and aspirating needle because they had been known to cause death from hemorrhage.

Cancer Significance of Mammary Adenoma.—Dr. WILLIAM J. GILLETTE of Toledo, Ohio, said that adenoma of the primary type or stage in individuals under 30 years of age might be removed together with their capsule and a wide markin of the adjacent stroma and a very favorable prognosis furnished, but in women over 30 years of age even this type should be considered potentially malignant. Cases of secondary hyperplasia should be considered as precancerous, and while they did not require so extensive an operation as the removal of the underlying muscles together with the axillary glands, yet no portion of the mammae should be left. The tertiary type was fully developed cancer and should be treated as such. He would urge the early examination of all neoplasms of the breast by the pathologist, and upon his advice that the growth was adenoma that the surgeon be ready to immediately carry out such radical procedure as might be necessary to deal properly with its type. With all due deference to the conservative pathologist, clinical experience proved that so-called benign adenomas of the mammary gland were often anything but benign. The teachings of such men as MacCarty, Ziegler, Bloodgood, Mallory, Bainbridge, Means and Moseley were pretty generally accepted that conditions did exist and were recognizable, that could be considered as precancerous.

Cancer in Women: Educational Cancer Campaign Among the Medical Profession and the Laity.—Dr. ANDRE CROTTI of Columbus, Ohio, stated that one of the outstanding features among the causative factors of cancer was chronic irritation, and while researches must still go on in the laboratories until something better was found, all that we could do for the present from a practical point of view was to take this valuable piece of information into serious consideration and learn furthermore to detect the disease in its incipiency. The facts brought out by the Pennsylvania Cancer Committee were as follows: (1) On the average the patient's physician had known of the conditions present for one year in superficial and thirteen months in deep-seated cancer before any treatment was instituted. (2) Of superficial cancers only 68 per cent. and of deep-seated cancers only 48 per cent. were operable when

first seen by the surgeon. In 39 per cent. of the superficial cancers and in 46 per cent. of the deep-seated cancers there had been a precancerous condition, that was, a lesion which might have been cured, by comparatively simple operative measures and the ensuing cancer prevented. (3) In superficial cancers, symptoms of the condition were apparent to the patients on an average of eighteen months before the surgeon saw them; in deep-seated cancers the average was fourteen months. (4) In 3 per cent. of the cases of cancer of the breast the physician first consulted failed to make any local examination, while in 13 per cent. he gave mal advice, to use local applications, or "to wait and see what developed." (5) In stomach cases the physician made no local examination in 9 per cent., and gave mal advice in 20 per cent. (6) In cancer of the cervix there was no local examination in 10 per cent., and mal advice in 20 per cent. For the body of the uterus the figures were 10 per cent. and 10 per cent.; for ovarian 14 per cent. and 14 per cent., respectively. The most efficient way to come in contact with the public was through the newspaper. The assistance of newspapers should be sought to spread knowledge of the cancer problem. This must be done in a dignified but persistent way.

Tumors of the Breast, Based on a Study of Seventy-seven Cases Personally Observed.—Dr. MILES F. PORTER of Fort Wayne, Indiana, said that the present study was based upon all of the cases of tumor of the breast that had come under his observation since November, 1905, except a few cases, perhaps 25 or less, that were operated upon either in private homes, or outside hospitals, or under other circumstances which rendered the keeping of anything like adequate reports impossible. Of the 77 cases reported, 49 were malignant and 28 were benign. The types of malignancy observed with the number of each type were as follows: Adenocarcinoma, 7; scirrhous carcinoma, 17; duct cancer, 4; lymphosarcoma, 1; gland cell carcinoma, 1; squamous carcinoma, 2; medullary carcinoma, 2; metastatic carcinoma, 1; cylindrical cell carcinoma, 2; not classified, 12. In 11 of the cases there was, in addition to the tumor present, either depression of the nipple, ulcers of the skin, or fluid discharging from the breast. The fluid discharge was in some cases colorless and in others bloody. The youngest patient in this group was 17 years of age. The oldest patient was 71. She had a scirrhous cancer. Thirty-three of the women had nursed children and of these 25 had malignant tumor. Of the 42 women who had tumors of the breast and who had not nursed children, only 19 had malignant tumors. Fifty-seven of these patients were married. Of the women over 25 years of age in his State (Indiana), 65 per cent. were either married, widowed or divorced. In his series of cases, 76 per cent. of the malignant tumors of the breast occurred in women who had nursed children, while only 24 per cent. occurred in single women, and 43 per cent. in women who had not nursed children. In 42 cases a primary radical operation was done. In 14 cases a radical operation was done following an excision of the tumor and an examination of a frozen section. In 12 cases the gland only was excised. In only a little more than 50 per cent. of the malignant cases was an immediate radical operation regarded as necessary. There was no operative mortality. Our only hope in improving the results in the treatment of cancer lay in earlier operation.

Some Lessons from the War for Abdominal Surgeons and Others.—Dr. ROLAND E. SKEEL of Cleveland, Ohio, stated that tetanus antitoxin as a prophylactic measure was of unquestioned value, when properly administered. That prolonged rough handling of abdominal viscera and traction on mesenteries was productive of shock lay within the experience of every abdominal surgeon, while shock as the result of moderate hemorrhage plus prolonged etherization was occasionally seen, but there still remained a residuum of cases in which none of these were operative, therefore Henderson's theory of carbon dioxide exosmosis or Cannon's of the development of a toxin in devitalized muscle might be called upon to explain. The value of certain procedures in treatment were definitely established clinically by the experience of war. These were, first, relief from extreme pain; second, the warming up of a patient who was cold; third, that hot liquid food was a decided stimulant; fourth, that the use either of saline or sodium bicarbonate solutions intravenously, subcutaneously or per rectum was of value as a temporary expedient only, and, fifth, that blood transfusion was applicable to more cases than any other one measure in overcoming any and every type of shock other than that of psychic origin. But little of importance was gained in our knowledge of intraabdominal injuries. Two things only stood out with any distinctness. The first of these was the fact that the most extensive injuries to the liver were not incompatible with life, unless the injury was of such character as to be almost immediately fatal. The extent of liver destruction which still permitted of recovery was a perennial source of astonishment. One of his own cases that recovered lost a transverse section of the entire upper abdominal wall some three inches in width with a groove in the liver substance which almost bisected it. In fact, the lower half of the liver was stitched into the defect in the abdominal wall to prevent extrusion of the intestines. The other was first pointed out to him by Major John Anderson, and had reference to the almost constant ratio between preoperative pulse rate and mortality in perforating abdominal injuries. A penetrating wound of the thorax and lung, even with extensive hemorrhage, which did not permit the ingress and egress of air with each respiratory movement came to be the subject of marked conservatism unless the resulting hemothorax became infected. Quite the contrary was true of open sucking wounds of the chest. The profound shock and appearance of impending death never were overcome until the entrance and exit of air were prevented by some kind of closure of the chest wall, the effects of which were almost instantaneous in their appearance.

JOINT SESSION WITH THE INTERSTATE ASSOCIATION OF ANESTHETISTS.

The Administration of Anesthesia in Obstetrics, Gynecology and Abdominal Surgery: Safety Factors in the Teamwork of Operator and Anesthetist.—Dr. JOHN J. BUETTNER of Syracuse, New York, said that one could state with perfect safety that teamwork in surgery had its advantages. It was no longer an experiment, but rather a well-established fact. Encouragement was given the anesthetist, who, being recognized as a full-fledged specialist, assumed his place in the surgical team, not alone as the one who administered the anesthetic, but as a consultant. He helped weigh in the balance the advisability of operating, the selection of the time that would be safest to operate, and made the choice of the anesthetic. He helped to prepare the patient for operation. To do this the anesthetist must be a trained physician. A further object of this trained surgical team was not alone to prevent death but to overcome or, at any rate, minimize the discomforts attending surgical operations. This training having brought about specialization, in turn encouraged further study and the discovery of new and hidden paths that would otherwise be unknown. The duty of the anesthetist was not merely to administer the anesthetic agent, but to help prepare the patient for the operation. When should he begin and what preparation was needed? When it was possible, the anesthetist should begin his work when the surgeon had decided that an operation was needed. It was advisable to have the patient in the hospital at least 48 hours before the operation. For some cases it might take several days to a number of weeks to properly prepare the patient. A full physical examination of the patient was advisable. With this there should be a quantitative and qualitative examination of the urine. We were no longer satisfied with a simple chemical examination of the urine. A full knowledge of the quantity of the urine for twenty-four hours, specific gravity, presence or absence of albumin, sugar, acetone, diacetic acid and casts. When possible a functional test should be made. The examination of acetone before operation was too often neglected. It should be made a routine practice. A full blood examination, including the clotting time of the blood, was another safeguard. One of the most trying and obstinate discomforts that was encountered at times was acidosis. The laboratory

could be of great help to us in this condition and proper diet and medication would overcome or mitigate this condition to such an extent that surgery could be undertaken with perfect safety. The laboratory work in diabetic cases was of inestimable value. It was especially in genito-urinary surgery where this preoperative cure and preparation of patient showed up so vividly. With this preoperative care, patients that formerly were doomed to die without operation were now made fit subjects for surgery that afforded not only relief, but oftentimes cure. At any rate, comforts were given where only misery was possible before. The one great field that was surely but slowly adopting gas oxygen was obstetrics. Chloroform had done noble work in obstetrics. It would never be totally replaced by gas oxygen or any other anesthetic. It was a very valuable anesthetic agent, when properly used and in properly selected cases. Ether would, of necessity, be the agent most largely used. It had its indications and in many cases its advantages over any other anesthetic. No doubt the difference in cost had been a drawback to the greater use of nitrous oxide. Greater experience had thus been gained with ether and when properly administered compared quite favorably with gas oxygen. The success of the administration of any anesthetic agent lay absolutely with the administrator rather than with the agent or apparatus used. Lastly, he would urge, first, a change in college curriculum to meet suggested requirements; second, a greater preoperative care and examination of patient; third, greater teamwork in our hospitals.

Some Adjuncts Which Promote Efficiency in the Use of Local Anesthesia.—Dr. Robert Emmet Farr of Minneapolis stated that the elements which had largely influenced him in the adoption of the present attitude regarding local anesthesia might be enumerated as follows: First, a realization that liberal amounts of novocain could be used if properly safeguarded; second, the development of an improved armamentarium; third, the development of a morale on the part of his assistants and the hospital attaches which, together with the gradual education of his clientele, greatly influenced the mental attitude of prospective patients, and, fourth, an improvement in the method of handling the tissues. At the present time, all of his operations were begun under local anesthesia, with the exception of cases in which it would be obviously impossible to handle the condition by this method. While local anesthesia had many shortcomings, because certain operative procedures could not be carried out under its use and certain patients would not submit to it, it was his belief that faulty technic was responsible for the vast majority of failures. Take, for example, a simple laparotomy for the removal of the appendix and shortening of the round ligaments, a perfect local anesthesia would allow us to complete this operation without touching the viscera within the pelvis except where it was necessary to attack the round ligaments and cecum. No gauze was necessary for packing off intestines and all pelvic viscera might be examined as at autopsy. The ideal sought was a complete abolition of the reflexes of the abdominal wall, with its resultant relaxation, and a negative intraabdominal pressure like that seen at autopsy. This was accomplished by a perfect anesthetization of the line of incision, painlessly produced, and gentle vertical retraction of the abdominal wall. Exposure of the viscera was facilitated by the use of gravity, the Trendelenburg position and lateral tilting, etc. To his mind the most important point was the careful introduction of the drug, and it was in attention to small details that success was achieved. In all of his abdominal work, except in the operation for inguinal hernia, a direct infiltration of the tissues was effected and the complete infiltration of the abdominal wall was made before the incision was begun. This method was chosen because of its efficiency, simplicity, accuracy, and speed. It was not used in the case of inguinal hernia because the infiltration of the tissues obscured to some extent the anatomical relations. His experience led him to believe that postoperative ileus and gas pains were, in the absence of infection, directly proportionate to the amount of trauma employed during the operation. Nausea and thirst and vomiting, with its disagreeableness and its sequelæ of wound strain and pain were largely eliminated. When operating upon children under local anesthesia restraint was necessary while the anesthetic was being introduced. His experience with more than 100 operations performed on children under the age of fifteen showed that the restraint necessary was probably less than 10 per cent. of that required during the administration of a general anesthetic, and that this class of patients lent themselves exceptionally well to this form of anesthesia.

Surgical Barrage.—Drs. Charles W. Moots and Elmer I. McKesson of Toledo, Ohio, stated that a surgical barrage might be defined as the process of surrounding the surgical patient with all the skill and refinement known to specialists in the various departments of medicine and surgery during the preoperative, operative and postoperative periods. Surrounded with such a barrage, the patient might reasonably anticipate the lowest possible mortality rate, with the shortest and least uncomfortable morbidity period, the latter factor becoming more and more the aim of every thoughtful surgeon. The gynecologist probably came in contact with a higher percentage of chronically ill patients than did any other surgeon. He must, therefore, consider with unusual care the preoperative and postoperative periods. Everything possible must be done not only to raise the patient's physical condition to the highest point of resistance, but her psychology must receive special attention. She should reach the hospital and be received without an unpleasant experience whenever possible. Immediate preoperative purgation was to be avoided. Fluids, especially alkalines, were given freely. A good night's rest was assured by the use of sedatives and, if absolutely necessary, some narcotic. They assumed that a positive diagnosis has been made, if such were a human possibility, and the work well planned before the hour of operating. This bespoke smooth, rapid surgery, without bungling haste. All known means should be used to measure the patient's resistance, including carefully acquired knowledge of the kidney function and cardiovascular system, as well as metabolism in general. They still continued to attribute much importance to the pulse pressure ratio, a term used to indicate the relation between the pulse pressure and the diastolic pressure, and which was discussed at length in a former paper read before the society. They had made systematic use of the principle ever since that time, just as they did for some years previous to the report. All cases were recorded and the records comprised most interesting data for study. The question of the advisability of nurses administering anesthetics had recently been brought up. It was their conclusion, after an impartial study of the subject that while many nurses might be taught to administer the safer agents in uncomplicated cases in a manner highly satisfactory to the operator, yet the principle was fundamentally wrong for reasons so numerous that they hesitated to embody them in their paper. They still maintained that the administration of a general anesthetic was the giving of the most powerful and dangerous drug at the most perilous time of the patient's life. During any major operation the anesthetist might be called upon to make one or several new diagnoses and prognoses, and this certainly constituted the practice of medicine and even demanded unusual skill. Circulatory depression or decompensation was best divided for surgical operation into three degrees: (1) Safe, 10 to 15 per cent. increase in pulse rate without change in pressure; 10 to 15 per cent. decrease in blood pressure without change in pulse rate. (2) Dangerous, 15 to 25 per cent. increase in pulse rate with 15 to 25 per cent. decrease in blood pressure. (3) Fatal, progressively increasing pulse rate above 100 with progressively falling blood pressures of 80 or less systolic and 20 or less pulse pressure, for more than 20 minutes. The first degree was never fatal but might gradually merge into the second degree, beginning shock, might be regarded as dangerous in the sense that it exhausted the heart and disarmed it for defense against continued low blood pressure. The third degree was always dangerous to the life of the patient. A vicious circle was established, consisting of the low blood pressure, the reduced heart nourishment which in turn still further reduced the blood pressure, and so on

progressively. This usually developed within 20 minutes after the third degree depression occurred and when once well established proved fatal at once or at most within three days. Where nitrous oxide-oxygen was available in skilled hands, the war had corroborated their previous observation that this form of narcosis was one of the best shock prophylactics we had. It was not remarkable that nitrous oxide-oxygen should be safer in shock and in preventing shock than other anesthetics when one recalled the fact that muscles could not be paralyzed with it.

Postoperative Analgesia.—Dr. BERTHA VAN HOOSEN of Chicago said that postoperative analgesia meant a painless convalescence for surgical patients. Attention to every detail before, during and after operation, especially from the standpoint of pain production, would develop an analgesic technic which would reward the surgeon for his time and trouble. This technic should be directed toward the prevention rather than the relief of pain. It should include the avoidance of psychic trauma previous to operation, and tissue trauma during operation. Gas pains, thirst, emesis, and catheterization must cease being necessary certainties and become avoidable and infrequent occurrences. Scopolamine-morphine was the only anesthetic that gave one a perfect means of preventing psychic trauma previous to operation, and, unlike any other anesthetic, it was followed by a period of analgesia varying from eight to twelve hours after consciousness had been regained. It might be desirable to continue the analgesia for a longer time. If so, it could be done by prescribing scopolamine 1/200 grain with morphine 1/32 grain, or scopolamine 1/400 grain with morphine 1/64 grain every four hours beginning about four hours after the operation and continuing for 24, 36 or 48 hours according to the probable length of the period of postoperative pain. Convenient hours for giving this postoperative twilight sleep (for that was really the condition produced) were 12, 4, 8 A. M. and P. M. The factors in postoperative analgesia technique might be enumerated in order of their importance as follows: Scopolamine-morphine anesthesia; large enemata (4 to 5 quarts) given in one-half hour following operation and retained; frequent minute doses of scopolamin-morphine at regular intervals after operation and continued for the first 24 or 36 hours; the use of sharp instruments during the operation, avoiding blunt dissection; sponging gently and infrequently; a comfortable posture for the patient, with an effort to secure relaxation or support as might be required for the traumatized part of the body. The fear of operation which so often caused the patient to seek surgical aid too late was a testimonial to the little attention surgeons had bestowed on this subject. By analgesia technique the old laborious, worrisome first two days after the operation would be transformed into a much needed rest and quiet. The hospital would be free from the odor of ether, enemata and vomitus, the groans of suffering patients, the frequent ringing of bells and the insistent demands for something to relieve thirst. When patients were comfortable or sleeping relatives would willingly refrain from long and frequent visits. Interns would not be wakened at night by nervous and restless sufferers and the surgeon would have patients who no longer looked upon an operation with dread and terror, but who would encourage their friends to take advantage of a cure by painless surgery.

Destruction of the Louvain Library.—The extent of the vandalistic work of the Germans at Louvain is now fully appreciated. The destruction and pillage went on during Aug. 25 to 30, 1914. Magnificent wainscotting, antique sculptures, portraits of Erasmus, Lipsius, Jansen, collections of manuscripts, the famous example of vellum presented to Vesalius by Charles the Fifth, the volumes of the library, the MS. of the forthcoming edition of Van Gehuchten on the anatomy of the human nervous system along with other valuable MSS. and records of the Faculty were all deliberately destroyed by order of the high command. Van Gehuchten went at once to the University of Cambridge to continue his labors, but died a few months later of volvulus.—*Gazette hebdomadaire des sciences médicales de Bordeaux.*

Therapeutic Hints.

Medical Treatment of Graves' Disease.—After curing several cases of Graves' disease of recent origin by the use of the old liq. iodi fort. alone, Henry Bazett found that he got better results with less irritation, by the use of a combination of Ung. Hydrarg. Co. with Ung. Iodi of the British Pharmacopœia. He cites a case of bilateral goiter, in a woman of 38, who had been operated on at the age of 32, when the thyroid gland of her right side was removed, the left gland not being touched. On July 6, 1918, upon finding a left-sided goiter of extraordinary hardness, accompanied by incessant distressing palpitation and other nervous disturbances, Bazett prescribed 15 minims daily of Donovan's solution internally, and the following ointment for constant application externally:

Glyc. belladonnæ	1 part
Ung. iodi	2 parts
Ung. hydrarg. co.	4 parts
Ung. plumbi subacet.	6 parts

By August 20 the goiter had practically disappeared. A year later the gland, perfectly soft and natural, could just be felt. The "illness" of which the patient complained when the treatment was first instituted was attributed by Bazett to the excess of the disappearing glandular substances in the blood owing to its very rapid dispersion.—*The Practitioner,* November, 1919.

Xylol in Dermatology.—The antiseptic and parasiticidal properties of xylol have been utilized by L. Bory in many dermatological conditions. As an ointment for herpes circinata, sycosis, impetigo, echthyma, folliculitis, eczema (after the acute stage), and for pediculosis pubis, the following ointment is recommended:

Iodine	1 g.
Xylol	15-20 c.c.
Soft paraffin	to 100 g.

For wounds as a first dressing the following modification is used:

Iodine	1 g.
Xylol	20 c.c.
Liquid paraffin	80 c.c.

For the treatment of soft sores and their complications:

Iodoform	10 g.
Xylol	20 g.
Soft paraffin	to 100 g.

A useful application for psoriasis is:

Coal-tar	3 parts
Xylol	1 part

—*Jour. des Praticiens.*

Lactic Lemonade in Intestinal Affections.—Following the work of Giani Moruzzi, and Zoja, with the use, clinically and experimentally, of a serum peptone, fermented by the lactic acid bacillus, in the treatment of intestinal affections. Gpeza employed a liquid diet composed entirely of a lactic lemonade according to the following formula:

Ox serum	500
Lactic acid	14
Sugar	250

In a large number of serious intestinal affections, including dysenteric enterocolitis and typhoid fever, good results were obtained.—*Le Progrès Médical.*

THE MODERN MEDICAL TREATMENT OF CHRONIC ULCER OF THE STOMACH AND DUODENUM; WITH SPECIAL REFERENCE TO THE SIPPY METHOD.*

BY SAMUEL WEISS, M.D.,

NEW YORK.

ATTENDING GASTROENTEROLOGIST, PHILANTHROPIN HOSPITAL; LECTURER ON MEDICINE, NURSES' TRAINING SCHOOL; FELLOW AMERICAN CONGRESS ON INTERNAL MEDICINE.

THE frequency of occurrence of gastric and duodenal ulcers varies with the statistics of various investigators; Weir's report, covering nearly 46,000 autopsies, shows 91 per cent. incidence of gastric ulcer and about a ¼ per cent. incidence of duodenal ulcer. These percentages agree with those established by Wille. Gruber, on the other hand, found gastric ulcer in 4 per cent. of autopsies.

The age incidence varies also with the particular experience of various reporters. Weir quotes Collins' statistics to the effect that in 297 cases of duodenal ulcer, the disease occurred 42 times in the first decade, 24 times in the second decade, 42 times in the third decade, 52 in the fourth, 46 in the fifth, 41 in the sixth, and 8 times in the seventh and eighth decades. The average age, according to Eusterman of the Mayo Clinic, of patients with gastric ulcer was 36 years. Peptic ulcer is not uncommon in later life, and also it has no relation to sex. As regards location of ulcer, Welch's figures, covering 793 autopsies, are as follows: 235 cases of ulcer on posterior wall, 288 on lesser curvature, 96 on anterior wall, 95 in pyloric ring, 27 in fundus, 27 along the greater curvature. In looking up the statistics covering the location of duodenal ulcer, I find that even more than the 95 per cent. stated by Coffey occur in the first part of the duodenum. George and Leonard in their book on "The Roentgen Diagnosis of Surgical Lesions of the Gastrointestinal Tract", state that whenever they determine the first part of the duodenum to be normal, they furnish a negative diagnosis regarding the existence of duodenal ulcer.

Regarding the etiology of peptic ulcer, it is rather a fruitless effort to restate at length the various hypotheses that have been framed to meet the problem. It seems to be important to be able to tell whether the focus is in the gall bladder or appendix, as Moynihan claims it so often is, or whether the focus is a cryptic or patent streptococcal lesion situated elsewhere.

*Read in abstract at the meeting of the Clinical Society of the Philanthropin Hospital, February 13, 1919.

Rosenow says: "Intravenous injection of streptococci of the proper grade of virulence may be followed by ulcer of the stomach and duodenum. The ulceration is due to a localized infection and secondary digestion. The ulcers are usually single and deep, with marked tendency to hemorrhage and perforation, and resemble the human gastric ulcer in many respects. When we take into consideration this close resemblance, that injection of streptococci which have grown in tonsils produces the lesion, and the virulence of the germs when the affinity for the stomach is the greatest is of such character that a general infection does not occur, it appears altogether reasonable to suppose that in man gastric ulcer may be caused by streptococci also. The supposed relation between the infected tonsils or gums and gastric ulcer may be due, not to the swallowing of bacteria, as usually supposed, but to the entrance into the blood of streptococci of the proper kind of virulence to produce local infection in the wall of the stomach. Many other observations may be cited, such as associated infections of the gall bladder and appendix, which suggest that gastric ulcer may be due to streptococci."

It is practically impossible for anyone of experience to discuss the subject of gastric ulcer with any definite diagnostic scheme in view. The cardinal symptoms of pain, vomiting, hematemesis, and stagnation still stand, but must be interpreted with great care for detail, and even then we find ourselves usually placing most reliance on the type of pain complained of by the patient. The pronounced advance made in the field of *x*-ray diagnosis offers much aid and will be discussed later.

The typical ulcer pain develops from half an hour to two hours after eating, and develops gradually; is burning, boring, cutting, or stabbing; is localized in the middle line, close to the ensiform cartilage, possibly radiating to the back of the precordium; is regular in occurrence and is induced principally by solid foods, and rarely by water; it lasts for some time and is often terminated only by vomiting or by the ingestion of alkalies or albuminous foods. The tenderness is pronounced, and is sharply localized over a small area in the middle line between the ensiform cartilage and a point midway down the umbilicus. Vomiting is not at all essential to the clinical picture. Actual hematemesis, taken with these symptoms, is almost absolutely diagnostic. Hyperchlorhydria is not rarely found; it is contributory evidence, but it does not rule out carcinoma. In gastric ulcer hypersecretion is even a more constant finding than hyperchlorhydria.

Regarding the diagnosis of duodenal ulcer, the classical symptoms described by Moynihan represent an authoritatively confirmed opinion. The patient complains of certain definite attacks; and if the history is taken in detail, letting the man tell his own story, he will give the impression of having read something which has been written about duodenal ulcer. He says—that his trouble comes on in attacks which are nearly always worse in winter than in summer and are very apt to be precipitated by a chill. Let us follow the patient through the day. He takes a meal at eight in the morning, and for from two to two and one-half hours afterward he is fairly comfortable; it is his best time. Some of these patients develop a habit of belching. They may bring up a very sour fluid and get relief this way. They may bring up a very sour fluid, which tastes very bitter and acid, and makes the mouth dry and the teeth chalky. This pain gradually increases until the next meal comes. To this Moynihan some years ago applied the term of "hunger pain." At the next meal the patient almost instantly gets relief, and the relief persists for two or three hours again. He probably eats a heavy dinner, and he will nearly always tell you he has something before he gets into bed; a glass of milk or a cup of cocoa and a biscuit. He sleeps comfortably until about 2 A. M., and then gets relief again by nibbling a biscuit which he keeps at the bedside. The pain is found to be most relievable by something stodgy and indigestible. Taking an alkali relieves the pain; so will emptying the stomach by washing it out. If these symptoms which I have described are recurrent, one may diagnose duedenal ulcer.

Were it not for the corroborative aid of the *x*-ray, our subjective symptoms would mislead us and we should be left in the lurch very frequently. Carman, Cole, Mills, Case, George, and Leonard deserve much credit for the patience with which they have worked out the details of the *x*-ray diagnosis of gastric and duodenal disease.

Carman gives eight roentgenoscopic characteristics of gastric and duodenal ulcer as follows:—

For gastric ulcer: (1) Diverticulum of perforating ulcer. (2) Visualization of bismuth-filled crater of a callous ulcer. (3) The incisura, or transverse contracture, indenting the greater curvature. (4) Localized pressure-tender point on lesser curvature. (5) Residue after six hours. (6) Acute fish hook form of stomach, with displacement to the left and down. (7) Delayed opening of the pylorus. (8) Settling of the bismuth to the lower pole of the stomach, such as is seen in hypertonicity or atony.

For duodenal ulcer: (1) Early, free opening of the pylorus, with early clearing of the stomach. (2) Lagging of bismuth in the duodenum. (3) Residue in the stomach after six hours. (4) Pressure tender-point over the duodenum. (5) Dilatation of the cap. (6) Irregular outline of the cap or duodenum. (7) Diverticulum of a perforating ulcer. (8) Vigorous peristalsis, especially if there is obstruction.

There are four essential complications of gastric ulcer that call for special mention: progressive loss of weight, perforation of ulcer, acute hemorrhage, and the development of cancer on an ulcer base. The first complication, loss of weight, calls for no special comment, for it is merely consequent upon the vomiting that results either from pain and reflex pylorospasm or from organic pyloric obstruction following cicatrization. Of all the complications it is the one that responds most readily to proper surgical therapy.

Perforation is not only an acute complication, but also one of the gravest of intraabdominal lesions. Perforation manifests itself as an acute abdominal crisis, attended by the classical symptoms of acute peritonitis, ushered in usually by evidences of surgical shock. Moynihan calls attention to the so-called subacute perforations, in which the perforation is so small that the peritoneal cavity is not overwhelmed and is able to build up a barrier of adhesions. These patients present also the clinical signs of an acute peritonitis, but not so marked as in the case of large, sudden, acute perforations.

The question of cancer as a complicating feature of ulcer is secondary in importance to perforation only because it is not possible to demonstrate an indisputable causal relation between ulcer and cancer.

MEDICAL TREATMENT OF PEPTIC ULCER.

I. *Period of Observation and Differential Diagnosis.*—The patient upon entrance to the hospital is given a fractional test-meal, consisting of 15 grams of lactose in 300 grams of weak tea, and by means of a Rehfuss tube half-hourly aspirations are made and the material withdrawn is tested for free acid, total acidity, and sugar. The usual seven-hour motor meal is given the following day. On the third day of the examination the patient is fluoroscoped, using first a sediment mixture consisting of one ounce of bismuth or barium in four ounces of water. The purpose of this mixture is to show the tone and type of stomach also the presence of a niche or bud. This is followed by the usual buttermilk and barium mixture and *x*-ray plates are taken. I would emphasize the value and necessity of the personal observation of the clinician at the time of the fluoroscopic examination. Many times valuable points of practical aid in management are thus obtained. All the stools passed by the patient are sent to the laboratory and examined for occult blood, undigested food, and mucus. By means of these various examinations one should arrive at an accurate individual diagnosis; and it would seem almost unnecessary to emphasize the necessity of individualization in the diagnosis and treatment of gastric ulcer, for surely in few other diseases is the imperative necessity of such individualization more apparent. There surely is no such thing as a routine treatment of ulcer because of the variableness in the pathology and manifestations of this disease. One can not treat ulcer patients *en masse* any more than one can treat them upon the history and complaints alone, no matter how carefully obtained and skilfully analyzed that history may be. Further, the necessity of an accurate differential diagnosis is equally apparent. In scarcely any other intraabdominal condition is the differential diagnosis and the ruling out of nonulcerative conditions more difficult and more

important if one wishes to obtain successful results in the treatment. As is well known, the clinical complaints of ulcer patients are daily simulated in patients with diseases of the pelvic organs; in patients with intraabdominal adhesions; in patients with Bright's disease with hypertension and abdominal crises of pain; in chronic gallbladder and appendix patients; in various other diseases of the stomach and liver; in tabetic crises, etc.

Further, one should not be content merely with a positive diagnosis of ulcer, but one is interested and anxious to learn whether that ulcer is acute, subacute, or chronic; whether it is thickened, indurated, and associated with perigastric or periduodenal adhesions; whether it is associated with cicatricial hourglass stomach; whether there is an associated underlying disease, such as syphilis, tuberculosis, cancer, etc.; what the general condition of the patient is from the standpoint of severe secondary anemia, chronic blood-vessel disease, etc., etc.

It may not be out of place to mention very briefly the following: First, a patient in whom a diagnosis of chronic ulcer has been made, but in whom no attention was paid to the underlying chronic processes, failed to make satisfactory progress under the usual medical management until a positive Wassermann test had been obtained and the introduction of antisyphilitic treatment cleared up the picture. Another patient, who had been starved and treated by many excellent men for supposed ulcer, had in reality no ulcer at all, but a high-grade of gastroptosis, and under forced feeding in bed, with the foot of the bed elevated, gained 30 pounds in two months and the "ulcer" was cured. A third patient, who had a chronic duodenal ulcer and had in addition a slight evening rise of temperature with evidence of a thickened pleura on the left side, was cured after a six months sojourn in the country.

II. *Period of Absolute Rest in Bed and Starvation.*—The chief methods of dietary treatment for ulcer may be classed as: 1. Absolute physiological rest to the upper digestive tract with later mouth feedings either with or without rectal alimentation in addition.

2. Almost continuous, but reduced, physiological activity of the same region but with food that is in small amounts, principally protein, and which has the quality of quickly binding the free hydrochloric acid, turning the albumin into the comparatively unirritating syntonin, and of leaving the stomach quite promptly.

3. Transgastric or duodenal feedings.

4. An essential feature of still another form of treatment is the use of alkalies to reduce the exaggerated acidity, usually present in these cases, together with the feeding of small quantities at frequent intervals of highly albuminous foods. The use of alkalies may, of course, be combined with any one of the forms of treatment.

III. *Period of Beginning Feeding.*—There are several methods which have been in use and have their advantages and their disadvantages. To enumerate briefly we have: Von Leube Diet, which has been modified by G. R. Lockwood.

Lenhartz's Diet.

Diet combined with alkaline treatment. There have been advanced many forms of the alkaline treatment combined with proper diet for cases of gastric and duodenal ulcer, but apparently the one most specifically and carefully worked out for this treatment is that arranged and practised by Sippy of Chicago. By this method he feels that an operative procedure is scarcely ever necessary, as the cases are so regularly cured by medical means, and he has even included all cases of pyloric stenosis, except those of extreme narrowing, due to definite cicatricial contraction following a healed ulcer. He says that after three, four, or more weeks of this treatment the spasm is relieved, the round-celled infiltration disappears as well as the edema of the inflammatory tissues, and the lumen is again established so that in practically every case a motor meal, consisting of meat and vegetables, leaves the stomach within the normal limits of six or seven hours. This is, of course, quite radical and might be considered an extreme statement; Sippy, however, is most definite in his statements as to methods, what is to be expected and the results obtained, and since they are made on such responsible authority they warrant a respectful hearing and a very thorough trial in practice. He limits surgical interference to the following cases and complications: (1) Perforation. (2) Perigastric abscess. (3) Secondary carcinoma. (4) Hourglass or other deformity. (5) Hemorrhage of a serious nature under certain conditions. (6) Pyloric obstruction of high grade not influenced by medical treatment.

The underlying principles on which the diet and treatment are founded may be stated as follows: Peptic ulcers would tend to heal spontaneously, as ulcers situated elsewhere, were it not for the fact that they are constantly subjected to the corrosive action of the gastric juice, and if this can be neutralized continuously during the period of gastric and upper intestinal digestion by proper diet and alkalies and the removal at night of any product of continuous hypersecretion, the ulcer will heal without difficulty.

With the above as a basis, I have made use of Sippy's method in the treatment of cases occurring in my service at the Philanthropin Hospital, and through the kind cooperation of the house physicians, Drs. Essner and Jacobson, and Miss Merz, the head supervisor, I have obtained excellent results in treating cases which have been otherwise given up as incurable and were fit for the surgeon only.

The treatment followed was as follows: Patients are put to bed for from three to four weeks. It has been my practice in some cases to withdraw all food by mouth for the first four or five days. The patient is given a daily cleansing soapsuds enema every morning at 7 o'clock. Thirty minutes later he is given a suppository consisting of ½ to 1 grain extract of belladonna. At eight o'clock he is given a nutritive enema, and this is repeated at 12 o'clock noon, and at 4 and 8 o'clock P. M. If the patient is unusually restless or nervous 10 to 20 grains of sodium bromide may be included in one of the enemas. The enemas are given

slowly through a small soft-rubber catheter, inserted not more than two to four inches within the sphincter. In addition a Priessnitz binder is usually applied in the morning and left on the entire day, and, if not uncomfortable to the patient, during the night as well. While many patients might do just as well without the preliminary starvation period, in my experience it does them no harm, and, so far as can be judged, is of considerable benefit in allaying pain, vomiting, and nausea, and improving the general well-being of the patient. While this preliminary starvation period might well be cast aside in most cases, in patients with a bleeding ulcer I feel that it is absolutely necessary. The only difference in the treatment just outlined is that an ice-bag or ice-coil is applied to the abdomen instead of the Priessnitz binder, and sufficient morphine and atropine is given hypodermatically to insure complete rest of the gastrointestinal tract.

After the above starvation period mouth feeding is begun. Each morning one-half hour before the first feeding a dram of bismuth subcarbonate is given in a little water. Feedings are given every hour from 7 A. M. to 7 P. M., consisting of equal parts of milk and cream in amounts of a total of one to three ounces. Although acidity is more easily controlled by hourly feedings, some cases do well on two, three, or four hourly feedings. Half-way between each feeding a powder consisting of 10 grains each of calcined magnesia and sodium bicarbonate is given, alternating with another powder of 10 grains of bismuth and 20 to 30 grains of sodium bicarbonate. It is best to give the powder containing magnesia as often as possible, as the magnesia has four times the power of neutralizing the free hydrochloric acid as compared with the soda; diarrhea, however, is apt to follow its free use, so that one must alternate these powders according to this condition. After two or three days, soft eggs and well-cooked (fine) cereal are added, so that at the end of about ten days the patients are receiving the three ounces of milk and cream mixture every hour from 7 A. M. to 7 P. M., 3 soft-boiled eggs, one at a time, and nine ounces cereal, 3 ounces given at each of the three feedings. These extras are added one at a time until the six extra feedings of eggs and cereals are given evenly spaced throughout the day. The bulk of each feeding should not exceed a total of 6 ounces. In order that the treatment should be successful, an accurate control of the acidity must be maintained throughout the twenty-four hours. This is accomplished by testing the gastric contents from time to time, early in the treatment, by the stomach tube. Sippy's method for accurate control of the free hydrochloric acidity is somewhat as follows: the first day or two the tube is passed occasionally to check up the presence of free HCl; if this is present in the stomach contents, the alkali powders must be increased, as the treatment aims absolutely to keep the free HCl down to zero. After a day of two this is done as a routine two or three times a week, as practically that is all that is necessary to insure the absence of the hydrochloric acid.

The amount of alkali can be varied as determined by the examination of the stomach contents. It is particularly necessary to be sure that the stomach does not contain free acid during the night, and it may be necessary to give two or three alkali powders between 7 and 10 P. M. to insure this. At 10 o'clock the tube should be passed and all acid hypersecretion removed. If there is a considerable amount of this, the tube should be passed again during the night two or three times. After the first few days treatment this is rarely necessary, as the hypersecretion is usually well controlled and at 10 P. M. nothing but a very few cubic centimeters of gastric contents will be found and this is unimportant.

In the diet, cream soup, vegetable purees, or other soft foods such as jellies, custards, creams may be added or substituted; keeping, however, the milk, cream, eggs, and cereal as the basis of the diet. The best cereals are farina, cream of wheat, and rice cooked to a soft pulp. With this diet it is quite regularly that the patients show a gain from 1 to 4 pounds a week.

During the third week, soft toast or crackers, puree of potato, and cream soup may be added. In the fourth week the milk and cream may be made 2½ ounces each at each feeding, and the period between feedings may be lengthened to two hours. After two or three weeks more, three-hour feedings may be given, but if the ulcer is of some months' duration it is best not to increase the periods too rapidly, and for several months it is wise not to have the patients take less than five feedings a day. The morning bismuth should be taken for from six to eight weeks and then stopped, but the alkaline powders should be continued between feedings for several months.

During a period of a year or more, milk, cream, eggs, vegetables, purees, cereal, bread and butter, and meat should form the basis of the diet. In cases in which for one reason or another milk is distasteful, it often can be given if flavored with tea, cocoa, grape-juice, etc.; frozen balls of butter may be substituted for cream, and a small quantity of cereal gruel may be given each hour.

Ambulatory Diet Cure for Peptic Ulcer.—There are always a certain number of patients in whom the symptoms are very suggestive of chronic ulcer, but in whom the diagnosis is not sufficiently certain, or for one reason or another the patients will not or cannot give the time for a regular course of treatment in bed. In these cases it is advisable to put them on a bland diet which has sufficient food value to keep up the strength, which combines well with the usual large excess of free hydrochloric acid, and which is obtainable almost any and every where. If the case is actually one of gastric or duodenal ulcer the chances are very great that at least there will be decided temporary relief, sometimes for a year or more, and in a few cases, particularly if persisted in for three or four weeks, the writer has seen clinical cures. The diet is also of considerable diagnostic value, as the case which is clinically ulcer but does not get very great or complete temporary relief for weeks or longer, is very probably not ulcer but chronic appendicitis, gall-bladder disease, or something else which simulates ulcer.

The diet for these ambulatory cases is planned

as follows: For two or more weeks, they take at 8 A. M., 1, and 7 P. M., 2 glasses of milk and 2 soft-boiled eggs without salt at first. At 11 A. M., 4, and 10 P. M. 1 and ½ glasses of milk, and about 16 ounces of cream during the day.

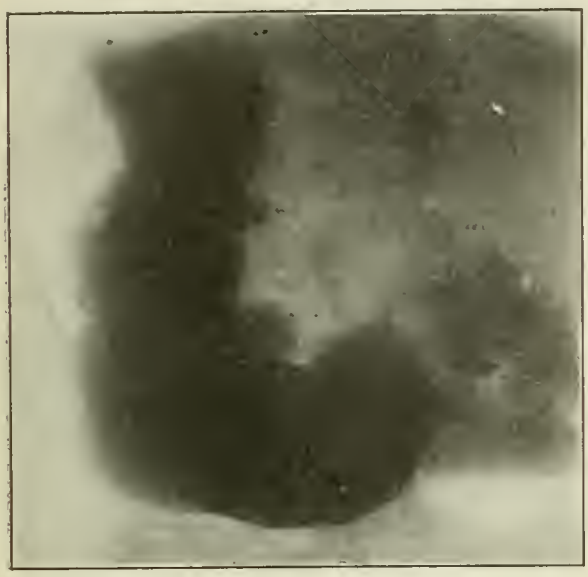

Fig. 1.—Mr. S.—Two Haudek niches, showing the presence of two chronic penetrating ulcers. See Figs. 2, 3, and 4.

After the two weeks are up, or later in severe cases, one can add fine well-cooked cereals, custards, gruels, cream soups, soft toast; and still later boiled fish, etc.

One does not expect to get the best results with this diet and it should not be advised unless the patient refuses for one reason or another to take a full course of diet with rest in bed. Vichy

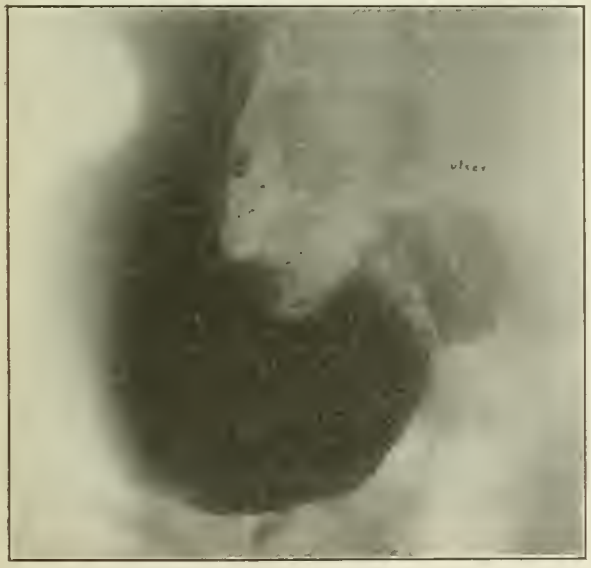

Fig. 2.—Mr. S.—Roentgenogram six weeks after beginning of treatment. See Figs. 1, 3, and 4.

is the best form in which to take water between feedings, or if more alkali is indicated by much acidity, alkali powders may be given an hour or an hour and a half after the principal feedings. If the milk mixture does not seem to agree, some of the alkali may be added directly to each feeding. An occasional case has to omit the cream on account of increased gastric acidity.

Follow-up System.—I want especially to emphasize the need of a good follow-up system in

Fig. 3.—Mr. S.—Roentgenogram eight weeks after beginning treatment. See Figs. 1, 2, and 4.

chronic ulcer. These ulcers are essentially chronic, and this should be carefully explained to the patient. The greatest failure I see in medical treatment is due to the failure to follow up the cases carefully for months, and to protect the stomach from irritation for a long time.

Every ulcer is different and needs careful watching and frequent modification in treatment.

Fig. 4.—Mr. S.—*X*-ray picture three months after beginning treatment. See Figs. 1, 2, and 3.

There is no such thing as ulcer treatment. We do not want to lose track of a chronic ulcer patient and have him report only when his symptoms are severe. Watch the patient with chronic ulcer and protect him from recurrence.

We do not depend simply on the patient's symptoms and general condition, we use the Roentgen ray freely to watch the anatomic changes in the ulcer and their effect on gastric function.

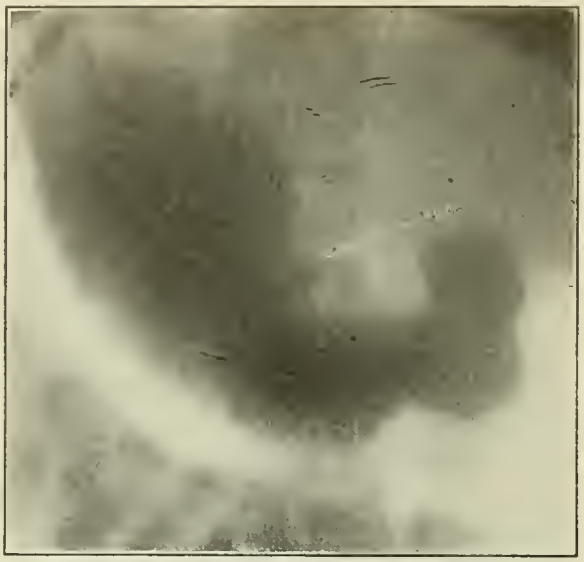

Fig. 5.—Mr. G.—The *x*-ray picture shows a penetrating ulcer on the lower curvature. See Figs. 6 and 7.

A follow-up system is equally valuable in cases after operation. In addition to judging the case by the general condition and symptoms, we can decide by the Roentgen examination regarding the anatomy of the ulcer, whether or not the new opening is working well, if it is in the right place, or too large or too small, whether or not food goes freely and promptly through it, whether the stomach empties too rapidly or too slowly. More than one examination is usually needed when

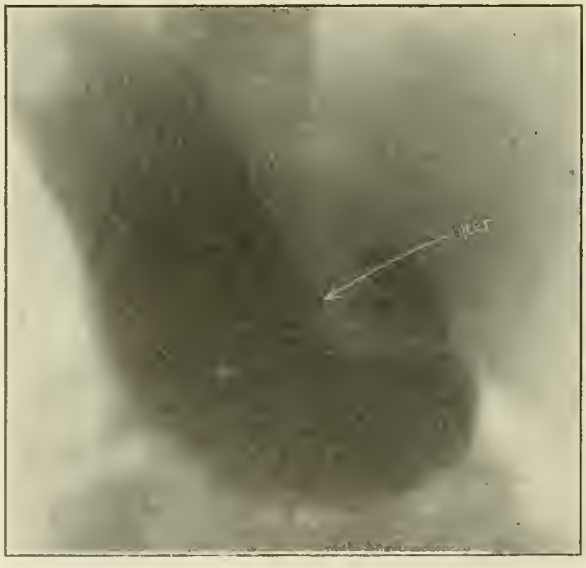

Fig. 6.—Mr. G.—Roentgenogram four weeks after the commencement of treatment. See Figs. 5 and 7.

stasis, spasm, or pocketing is found. These changes are often variable and may entirely disappear after the use of atropine.

This medical treatment of ulcer cases after operation is very important. The surgeon frequently tells his patient after operation that he is now perfectly well and can do anything he likes. I have a number of patients in whom the old symptoms of acidity, distress, pain, and vomiting returned—not in the first weeks or months after

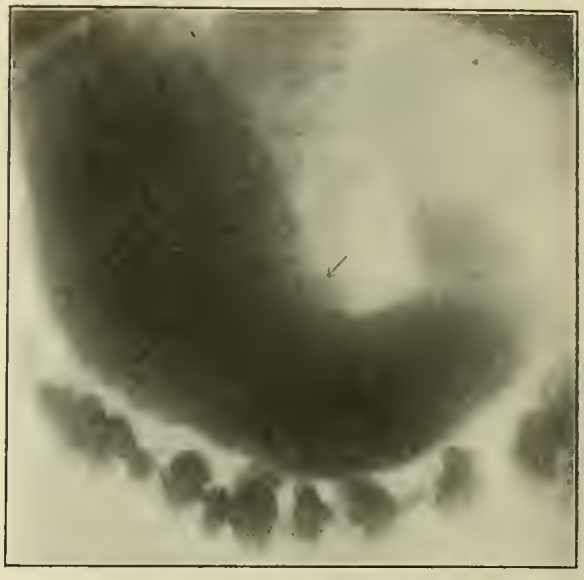

Fig. 7.—Mr. G.—X-ray picture taken three months after the beginning of treatment. See Figs. 5 and 6.

operation, but six months or more later. Examination almost invariably shows that the patient has become careless in various ways in regard to diet, mental strain, the abuse of tobacco or alcohol. Frequently the examination shows a tendency to hyperacidity and spasm. The stomach is usually empty in the normal time. We have here an irritable stomach, not another ulcer, and a short course of ambulatory medical treatment has almost always checked these symptoms. I firmly believe that some regular medical advice and follow-up system are desirable in all surgical ulcer cases.

Medical treatment, properly used with the new and more exact methods we now have for diagnosis and observation, will cure more chronic ulcers than surgery. Not necessarily because it is better treatment, but because it is always used first.

What are the signs of cure of an ulcer? A long period of freedom from symptoms, say six months or more, the longer the better, combined with normal gastric functions, absence of blood in the stools, and a marked or complete change in the anatomy of the ulcer. When an ulcer reappears after such an event, I think we are justified in calling it a new ulcer, not the recurrence of an old one. Ulcers in hospital patients recur much more frequently than in the well-to-do, on account of coarse diet, alcohol, hard work, and unfavorable conditions, and therefore they need surgery more often.

The anatomical results of medical treatment of ulcer, as judged by the Roentgen examination of the patient, are very interesting. They are more easily studied in the ulcers along the lesser curvature which have definite craters; and also in ulcers of the duodenum where there is characteristic deformity.

Out of a group of about twenty medical cases which have thus far been followed for six months or more after medical treatment I have chosen a few to illustrate these points.

Fig. 8.—Mr. K.—Defective duodenal cap, due to chronic ulcer. See Fig. 9.

Case I.—Mr. S. Examination showed a marked hypersecretion on an empty stomach. Fig. 1 shows two pockets, or Haudek niches, on the lesser curvature as positive evidence of a double chronic penetrating ulcer. These pockets were constantly present at all examinations, made at different times under varying conditions. This patient was at the Philanthropin Hospital for a period of four weeks. Fig. 2 is the *x*-ray taken six weeks after commencement of treatment; that is, two weeks after he was discharged from the hospital. Fig. 3 is the *x*-ray taken eight weeks after commencement of treatment. Fig. 4 is the *x*-ray picture three months later.

Fig. 9.—Mr. K.—*X*-ray picture taken three months after the beginning of medical treatment. See Fig. 8.

It is remarkable what medical treatment accomplishes in these cases. The patient has gained in weight and at the time of his last *x*-ray examination he weighed 139¾ pounds. He was admonished to be careful of his diet and to keep up with his alkalies.

Case II.—Mr. G. gave a history of indigestion for the past five years. Fig. 5 shows a large penetrating ulcer on the lesser curvature. This patient was at the hospital for two weeks. Fig. 6 is the *x*-ray picture taken four weeks after the commencement of treatment. Fig. 7 is the *x*-ray picture taken three months later.

Case III.—Mr. K. Fig. 8 shows a defective duodenal cap due to chronic ulcer. Fig. 9 is the *x*-ray picture taken three months after medical treatment.

ROENTGEN DIAGNOSIS OF DISEASES OF THE THORACIC VISCERA.*

By JOSEPH S. DIAMOND, M.D.,

NEW YORK,

ASSOCIATE ROENTGENOLOGIST, BETH ISRAEL HOSPITAL.

Roentgenology in diseases of the chest approaches scientific precision. The interpretation of the various lesions rests upon the pathological processes taking place in the tissues. It is a visualization of the diseased organs *in vivo*, or "living pathology". A correct interpretation depends upon a knowledge of anatomy, histology, and pathology, and the more we are able to correlate the Roentgen shadows with the abnormal tissue changes, the more accurate will our interpretation become. This is perhaps best illustrated by the work of Miller and Dunham. The former analysed the pulmonary circulation, the lymphatic distribution, and their relation to the bronchi, while the latter built his pathological studies on the work of the former.

The physical diagnosis of percussion, auscultation, and palpation, like the Roentgen-ray studies, depends upon the changes of density in the tissues. These physical signs however require larger areas of involvement before changes in vibration and adventitious sounds reach the ear. Furthermore, they cannot be standardized, and will often be differently interpreted by different examiners, varying with the acuteness of perception of pitch. The Roentgen-ray examination however affords an instrument of precision, a uniform standard which will record the earilest tissue changes long before they will be discernible by means of the older methods of examination. We must, however, not minimize the importance of clinical study of each and every individual case, for what matters the findings of Roentgen signs, or even of physical signs of pulmonary tuberculosis when the patient has no manifestations of tuberculous toxemia such as tachycardia, elevation of temperature, night sweats, loss of weight, or asthenia? The final interpretation rests upon the clinical studies.

Examination of the Chest.—It is always advisable to follow a certain routine in the Roentgen-ray examination of the chest. We note first the type of thorax, whether narrow and elongated with a downward obliquity of the ribs corresponding to the *status asthenicus* of Stiller; or short and wide with the ribs joining the sternum at right angles as seen in the *status apoplecticus*. Wide interspaces are seen in the barrel chests of pulmonary emphysema.

*Read before the Yorkville Medical Society, May 19, 1919.

Scoliosis or other spinal defects will also cause changes in the width of the interspaces which may be wider on one side and narrower on the other. It is important to study the ribs, for we may often discover a synarthrosis as the result of a past

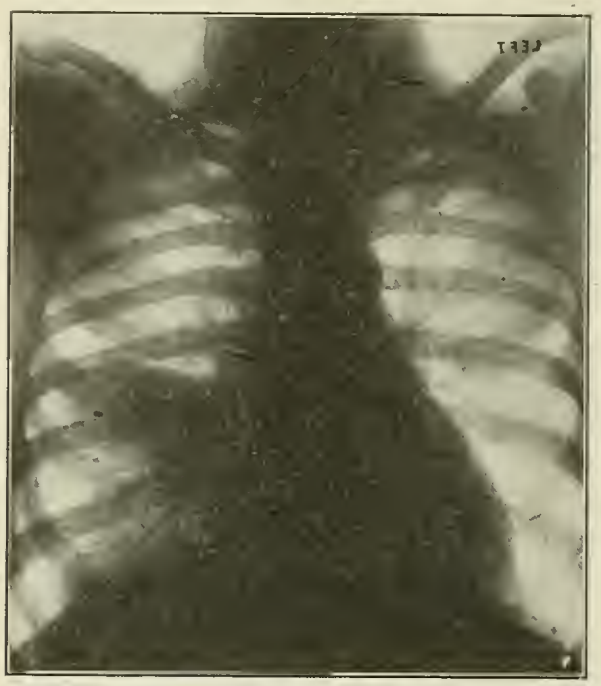

Fig. 1.—Pulmonary abcess, confined to right middle lobe; discovered by *x*-ray examination several weeks after onset of illness. Pus obtained on aspiration. Subsequent operation.

thoracotomy, such findings often giving the clue to the underlying pathological condition.

Diaphragms.—Next in order we study the diaphragmatic domes, their excursions, their shapes with each inspiration, the illumination of the costophrenic angles. The right diaphragm is always one interspace higher. When the left one is pushed up high by a distended gas bubble in the stomach, it is always indicative of chronic digestic disturbances. This often causes cardiac distress by an upward displacement of the left ventricle. Limited mobility of the diaphragm may indicate abhesions or inflammatory lesions of the lungs or pulmonary tuberculosis. The diaphragm may also be pushed upwards by a collection of pus underneath, as in subphrenic or liver abcess. Paralysis of the diaphragm, as in poliomyelitis, may also occur. Eventration of the diaphragm with upward displacement of the abdominal organs may take place, this being either congenital or the result of paralysis. Diaphragmatic hernia as a result of trauma, displacing an abdominal viscus into the pleura, may likewise occur. Downward displacement of the diaphragm with limited excursion occurs in pulmonary emphysema. In effusions the diaphragmatic outlines become obliterated.

Pulmonic Fields.—In examining the lungs we are struck by the brilliant illumination rediating through the pulmonary tissue. The large surface of alveolar air spaces allows this increased radiation. It is due to this factor that we are able to detect pathological lesions in the lungs. Any lesion, whether it be exudative or productive, will cause an increase in the density which will so alter the permeability of the rays in the involved area as to stand out strongly contrasted by the surrounding brilliancy of the normal lung tissue. By correlating the gross pathology of the various lesions, noting their size, shape, and location with the shadows cast, the degress of density, and diminished aeration, we have come to recognize with a fair amount of precision the type and nature of the disease. Even circulatory changes, such as occur in the passive congestion of cardiac diseases, can be recognized by the increase in the vascularity of the lungs, the lung markings appearing increased both in number and in size.

To recapitulate: Any deposition within the alveolar air spaces of adventitious substances, whether an exudate of red blood cells, or an infiltration of rounds cells, or a tumor mass, or lime salts, or a foreign body, will stand out as a denser area, the nature of which can be recognized by a preconceived knowledge of its pathological appearance compared to the degree of its radiability.

The Roentgen Anatomy of the Lungs.—We regard the lungs as two organs triangular in outline, situated on either side of the thorax with the apices above and the bases below. We study the hilus, the pulmonic markings, and the parenchyma.

Hilus: Rising from the mediastinum on either side of the lungs are the roots of the lungs, called the "hilus shadows". They assume the shape of the wings of a butterfly, the right more prominent than the left which is partly concealed by the left ventricle. The hilus shadow is a composite one, comprising arteries, veins, lymphatics, lymph nodes, bronchi, nerves and connective tissue.

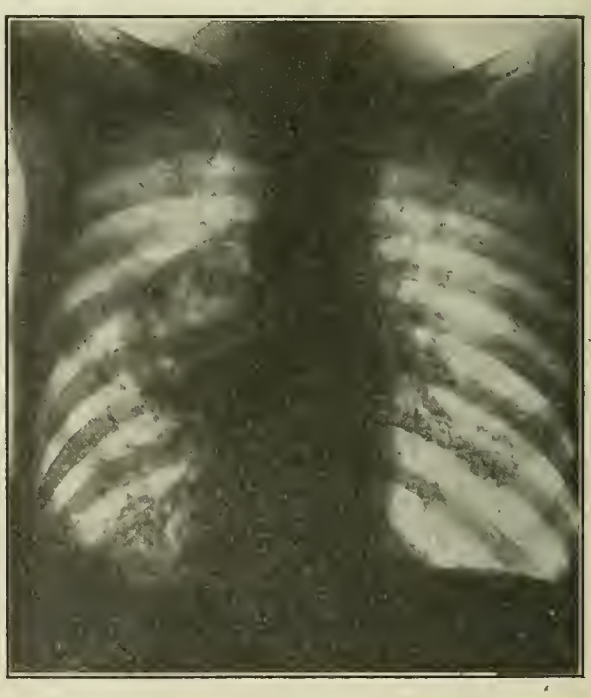

Fig. 2.—Pulmonary abcess of left lung following pneumonic process discovered several months after illness. Note capsule of dense fibrous tissue. Abcess multilocular. Note central location. Pus aspirated, and subsequently operated.

Pulmonic Markings: Springing from the hilus shadows and spreading in all directions are seen the pulmonic markings which radiate, divide, and subdivide in tree formation. They are heavier toward the hilum, become narrower toward the

periphery, and lose themselves as they reach the outer third of the pulmonic field. They are heaviest in the lower lobes. In the upper lobes the vessels are named according to their location. The first one extends along the vertebral column and is called the

Fig. 3.—Incipient tuberculosis—Note reduced illumination in right apex, engorgement of root branches and extension of markings into the apex and outer third.

vertebral branch. Another, rising in the first interspace, is called the first intercostal. Another in the second interspace is called the second intercostal.

Parenchyma of the Lung: The parenchyma of the lung is the major portion of the lung tissue and comprises the outermost portion, extending from the heavier trunks outward as far as the periphery. In the normal state it is seen as a clear, uniform, brilliantly illuminated area. It is important to study with care the illumination of the fields, as any mottling or disturbance in the uniformity of the illumination means pathology. We always compare the two sides. The apices of the lungs extend for one and one-half to two inches above the clavicles. They receive special study as they are the first vulnerable to pulmonary tuberculosis. Forced inspiration or forced expiration such as coughing will brighten the illumination in the normal apex, but will darken it when the apices are sclerosed or fibrotic—the so-called light reflex.

Mediastinum.—Next in order we study the mediastinum, which is centrally located and which contains the heart, the arch of the aorta and other large blood vessels, the trachea and subdividing bronchi, the paratracheal and bronchial glands, and the esophagus in the retrocardiac space. The mediastinal contents appear as a dark shadow due to the muscularity of the organs and to the large amount of blood in the heart chambers and vessels. They are further emphasized by the contrasting illumination of the surrounding lungs. In the upper mediastinum we may sometimes see a persistent thymus gland or a substernal thyroid. In studying the heart we note the size, the configuration of its borders, its position, and the pulsations of the left ventricles and auricles. In systole the apex retracts and the heart becomes smaller. With inspiration the heart becomes elongated and narrow. With expiration it becomes wider. In studying the aorta we note the ascending, the transverse arch, and the descending; the width of the arch, the expansile pulsation, and the presence or absence of aneurysm. The trachea is seen above in the midline, covering the spine as an illuminated band. We note its position.

The mediastinal contents may be displaced to either side. This may be due to either fluid or air in one hemithorax pushing the mediastinal contents to the opposite side; or they may be pulled by pericardial adhesions or by fibrotic changes in the lungs. When on the left, the apex of the heart may be displaced in extreme cases as far as the axillary border. The pleura and pericardium are not seen in the normal state. It is only when they become diseased and an exudate is thrown out that they cast shadows.

Inflammatory Diseases of the Lungs.—Bronchopneumonia: In this disease both lungs are affected. Numerous shadows varying in size are seen distributed throughout one or more lobes. These mottlings are due to infiltrations around the bronchi and to localized exudates in the alveoli, lobular in nature. Coalescense often takes place, resulting in larger areas of density covering sometimes an entire lobe. One can, however, always see areas of aeration shining through the density, denoting the unplugged bronchi or uninvolved lobules. This differs very strikingly from the lobar type, when

Fig. 4.—Chronic miliary tuberculosis. Note general distribution of peribronchial infiltrations scattered from apex to base throughout both lungs.

the exudate is uniform, filling up an entire lobe and conforming to its exact configuration. Consolidation or red hepatization begins at the periphery en masse and rapidly spreads inward toward the hilus. When resolution takes place it is a retrograde proc-

ess, the density clearing up first at the hilus and last at the periphery. In bronchopneumonia the infiltration starts from the hilus outwards. The old conception of a central pneumonia where no physical signs could be detected, yet the patient having

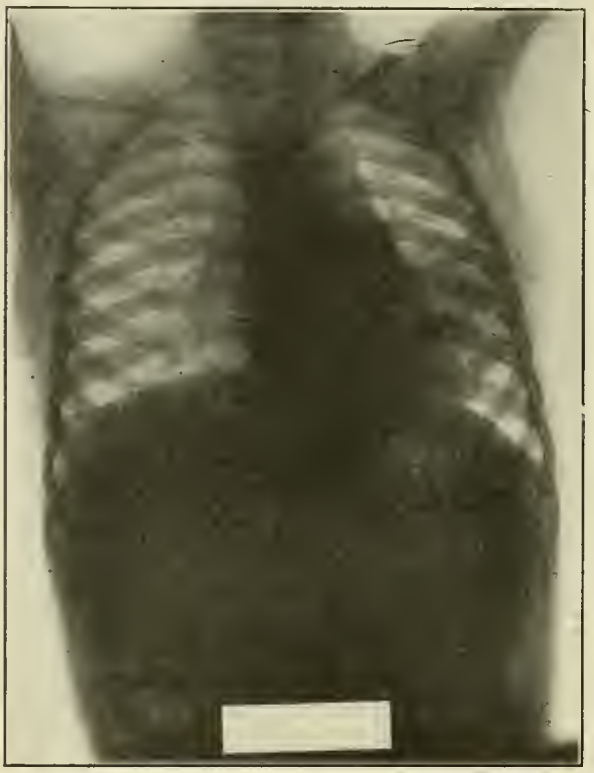

Fig. 5.—Bronchiectasis. Notice small area of infiltration in left lower lobe, through which are scattered several rounded areas of increased illumination, these representing bronchiectatic dilatations. This occurred in a boy following a foreign body pneumonia (aspiration of peanut shell, some of which was removed through bronchoscopy). Patient remained with a chronic cough and considerable expectoration; general condition good; *x*-ray taken one year later.

all other clinical evidences of pneumonia, was considered to be due to an exudate in the center of the lung and therefore inaccessible to the ear. As a matter of fact, these exudates are cortical, situated at the periphery and have not yet reached the hilus where the larger bronchi are situated; so the vibrations cannot be transmitted to the ear.

Pleurisy: Pleurisy with effusion casts a dense shadow and will cause a total disappearance of the lung markings. If the effusion be sufficiently large it will displace the mediastinal contents to the opposite side. The upper level of the fluid will assume a concave line, reaching higher at the periphery. This concave line is explained by Damoiseau to be due to the greater ease of compressibility of the lung at its periphery, where it is unattached and free, than at the root of the lung, where it is fixed. Hence the fluid rises higher at the borders. It is also explained on the ground of negative pressure present in the pleural cavity, the fluid being sucked up at the outer borders of the chest. This has an important bearing clinically, as we always look for flatness in the axilla in cases where we suspect fluid. When the negative pressure is absent in the pleural cavity and a positive atmospheric pressure is substituted, as in the case of pneumothorax, then the level of the fluid will be straight.

In encapsulated pleural collections such as interlobar or diaphragmatic encysted effusions the density is always seen in the periphery. In the interlobar condition the density is wedge-shaped with the base outwards. This is differentiated from a pulmonary abscess (Figs. 1 and 2) where the density seldom reaches the periphery. In an ordinary thickened pleura there is only a diffused density which is however sufficiently tran parent to allow the visualization of the lung markings. Difficulties of diagnosis arise sometimes in underlying consolidation when covered by thickened pleura.

Pneumothorax: In pneumothorax the lung is collapsed and usually lies against the spine and one can see the empty hemithorax without any lung markings. The diaphragm is displaced downwards and the mediastinum is displaced to the opposite side.

Pulmonary Tuberculosis: In considering the Roentgen appearance of pulmonary tuberculosis we must consider two types. One occurs in early life, in infants and children, and the other in adults. The first one is confined to the hilus of the lungs and appears as an infiltration of the glands at the roots. It causes a distortion of the natural butterfly outline of the hilus and may appear in extreme cases as a dense mass lying wedge-shaped, extending all the way out and approaching the axillary border with the base at the hilus and the apex at the periphery. This infiltration is called an adenopathy and is in itself not pathognomic of tuberculosis. Any disease which will cause a glandular enlargement of the root ,such as Hodgkin's disease, tumor, syphilis, or other form of infection such as whooping-cough, may give the same appearance. The clinical study of the case and the positive von Pirquet must determine the diagnosis. A D'Espine sign is present in all hilus infiltrations.

The study of the adult type of tuberculosis forms a fascinating chapter in the literature of the Roentgen-ray. Numerous investigators both here and

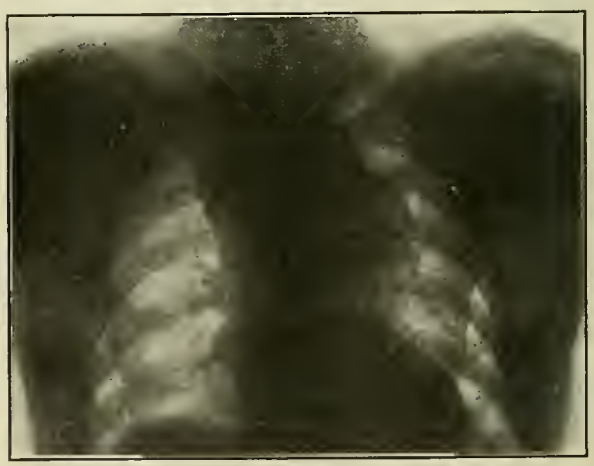

Fig. 6.—Lymphosarcoma arising from mediastinum and spreading through both left and right lungs. Note its sharp demarcation, almost simulating an aneurysm. This was of course differentiated by the lack of pulsations, irregular outline, and distribution.

abroad have worked in the interpretation of the tubercle in its various stages on the Roentgen plate. Miller has made a painstaking study of the bronchi and the pulmonary circulation, of the course and distribution of the lymphatic channels, lym-

phoid tissue, and their relation to the mucous membrane of the bronchi, ductus alveolaris, and pleura. K. Dunham has built upon this minute anatomy his pathological studies of the mode of invasion, and aided by the numerous sections of tubercular lungs

Fig. 7.—Pulmonary carcinoma, secondary to carcinoma of the left breast. Metastasis occurred five years later. Note effusion in the left chest, also small irregular infiltrations throughout the right lung, apparently rising from the mediastinum and spreading outward.

taken after radiography of the lungs *ex vivo* he has been able to correlate his studies with the appearance of the lesion on the Roentgen plates. It was found that the earliest tubercle forms in the lymphoid tissue at the periphery of the lung draining the ductus alveolaris. Simultaneously with this process there occurs a congestion of the blood vessels and an engorgement of the lymphatics which is characterized as an increase in the size and number of the linear markings. The hilus appears at this stage enlarged and shows evidence of glandular infiltration. The hilus is always affected more or less before any visible tubercles are seen in the parenchyma, the reason being well known; the lymphatics at first drain all the infected material, bacteria, and phagocytes into the natural "dustbins" of the human economy at the roots. Often the process stops here, the glands becoming in time inspissated with lime salts. This explains the frequency with which we see the hili studded with calcified glands in such a large percentage of normal individuals, confirming what Virchow said that "every one of us has a little tuberculosis."

When, however, the process does not stop here, and when the lymphatics become overloaded with infection and are unable to cope with the constant supply of infected material which is produced either because of the greater virulency or the lowered resistance, the tubercle forms in the lymphoid tissue situated around the smallest and most distant bronchioles, the ductus alveolares. It is seen as an irregular small area of increased density and spoken of as a peribronchial infiltration around the smallest bronchi. These infiltrations are first seen diffusely scattered through the upper lobes in the infraclavicular and supra clavicular regions at the periphery, and also intervene in the course of the linear markings (Fig. 3). The blood vessels are then engorged, especially the vertebral branch, and later the intercostal branches. The appearance of these is spoken of by Dunham as fan-shaped, with base to the periphery and apex toward the hilus. The blocking of the lymphatics adds to the engorgement and increases the prominence of the markings. The apex of the lung, due to the congestive changes, shows a reduced illumination and often a reticular network is seen through it. The above description is typical of an early tuberculous infiltration. A diagnosis of pulmonary tuberculosis can not, however, safely be made unless peribronchial infiltrations are seen, for congestion may be due to other causes. A reduced illumination in the apex may likewise be due to an old thickened pleura. A slight enlargement of the hilus with the presence of calcified nodes is usually found in a number of healthy individuals.

The peribronchial infiltrations may become larger by the invasions of the tubercles into the adjoining alveoli and interstitial tissue. These may fuse and occupy larger areas which are then spoken of as areas of consolidation. When in the acute state an exudate is thrown out into the alveoli, giving the appearance on the *x*-ray plates of a "fuzzy," "smoky," indistinct area with hazy and ill-defined borders, this is spoken of as the broncho-pneumonic type (Fig. 4). Later on these areas will undergo necrotic changes and when secondary infection sets in, will suppurate and form cavities. These cavities are seen as irregularly rounded areas of increased

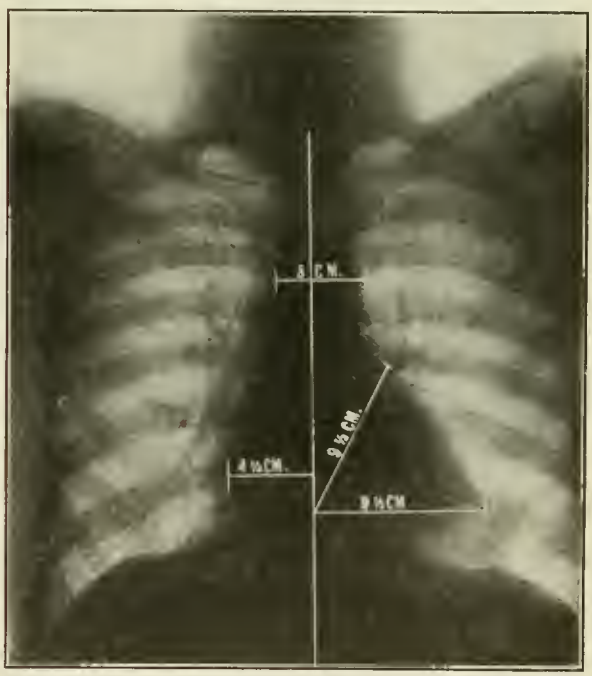

Fig. 8.—Normal Heart.

illumination of various sizes, smaller ones often branching together.

In tuberculosis the healing process is not a regenerative one. A tubercle does not undergo resolution as the exudate of a bronchopneumonia

does. It does not become absorbed, nor is there any replacement of new tissue. When the healing process takes place the tubercles undergo calcification or fibrosis. In the long-standing cases we may often see both changes, destructive and reparative, tak-

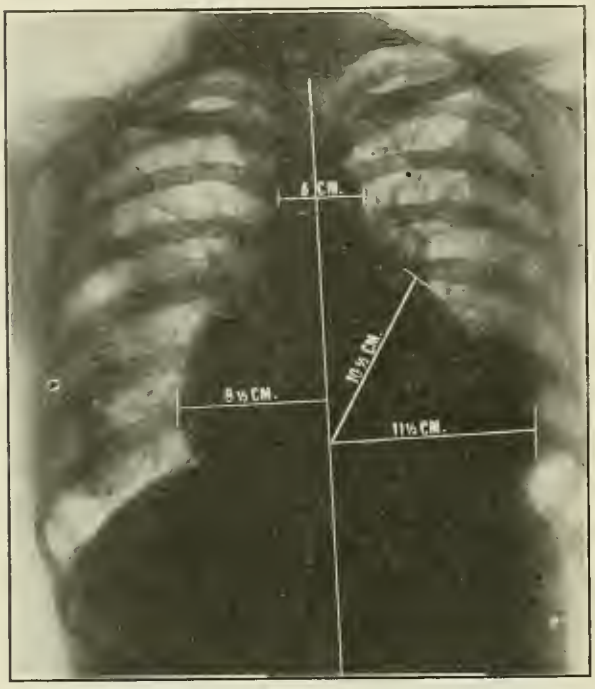

Fig. 9.—Mitral heart. Notice bulge of auriculopulmonic curve, recession of aortic arch, and dilatation of the right heart wall.

ing place simultaneously. The fibrotic changes may be very extensive and may be seen as bands running in all directions. All these various changes are well seen on the Roentgen plates.

The acute miliary type is seen as small, discrete, punctate areas of increased density scattered uniformly in large numbers throughout both lungs, from apex to base. As these originate from the blood stream their location is generalized.

Pneumonoconiosis: This is the result of irritative changes of the lungs due to the inhalation of dust, either metallic or carbon. The appearance of the lung on the *x*-ray plate varies with the stage of the disease. At first only congestive changes may be seen, a thickening of the trunk shadows. Later the deposition of the dust particles in the lymphatic structures causes certain densities to appear scattered symmetrically throughout both lungs. In time a characteristic mottled appearance becomes evident, which is distributed throughout the entire pulmonic field. At a certain stage of the disease it is often difficult to differentiate it from pulmonary tuberculosis. We must, however, bear in mind that pneumonoconiosis, in contradistinction to tuberculosis, does not begin in the apices; and also that the disease is symmetrical, while tuberculosis is irregular, asymmetrical, and always begins in the apices. Later in pneumonoconiosis fibrosis and bronchiectasis are common. Clinically, dyspnea is a marked feature in the later stages.

Bronchiectasis: Dilatation of the bronchi may occur at any age. It usually follows as the result of an acute infectious disease of the lungs, especially in influenzal broncho-pneumonia (Fig. 5). It may also result from fibrosis and chronic pleural affections, causing traction and distention of the bronchiel walls. Bronchiectasis can occur only when the deeper coats of the bronchi become involved. Several forms are recognized — cylindrical, fusiform, sacculated. These forms are all seen on the *x*-ray plates as areas of increased illumination, occurring usually in the lower lobes. The cylindrical occurs in the course of the large tubes and often tapers at the end, when it is called fusiform. The sacculated occurs in the terminal bronchioles and may reach large dimensions due to fusion of the distended air vesicles, the intervening septa undergoing atrophy. The surrounding tissue is usually the seat of atrophy.

Lung Tumors: Sarcoma and carcinoma are the most common tumors involving the lung. Benign tumors are rare. The malignant tumors are usually secondary, although they may occur as primary growths. The metastatic growth usually takes place through the chest when following breast tumors or may spread from the neck or mediastinum or from the upper abdomen through the lymph channels, draining through the diaphragh. Lung metastasis may also be hematogenous when spreading from distant organs such as the prostate. The sarcomata are usually easily recognized appearing as rounded dense masses usually well defined (Fig. 6). They are generally the lymphosarcomata, and as such are primary, springing from the glands at the root.

The carcinomata are very difficult of recognition, giving an irregular appearance of small areas of densities in the interstitial tissue of the lung and

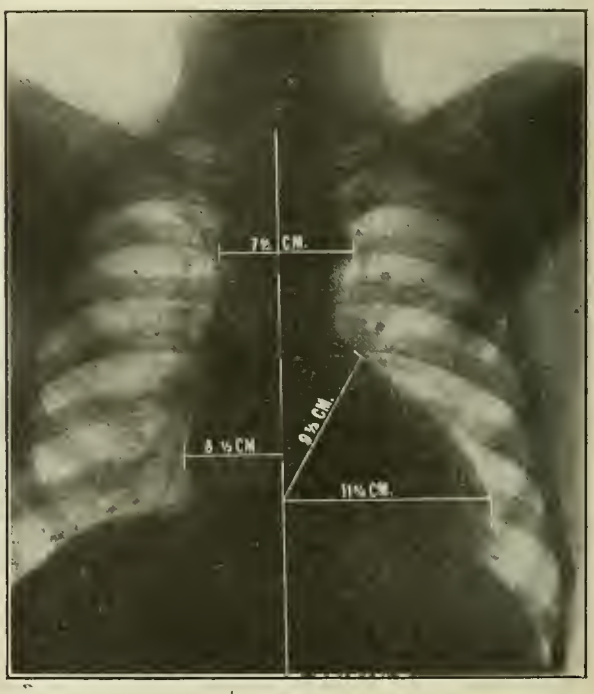

Fig. 10.—Aortic lesion. Notice accentuation of auriculopulmonic curve, width of aortic arch, and hypertrophy of the left ventricle.

following the larger trunks. When secondary, they are seen in both lungs. If the pleura becomes involved an effusion will result which, as is well known, is sanguineous in nature. The effusion is large and recurs repeatedly with many tappings.

Cysts: Echinococcus cysts have been reported, and may appear in the pleura, lung, or mediastinum. The appearance is that of a globular tumor mass. Their diagnosis, when in the lung, must be corroborated clinically by the presence of hooklets and

Fig. 11.—Immense aneurysm involving ascending, transverse, and descending aorta. Note large atheromatous plaque lining the descending aorta. According to the history the case was probably of ten years' duration. There were few postmediastinal pressure symptoms, the ascending arch being mostly involved and causing bulging of the anterior chest wall.

membranes in the sputum, and by the presence of eosinophilia.

The Heart: With the aid of the Roentgen ray the study of the size of the heart has become the most accurate form of examination as well as the simplest. Not only its size, but also the configuration of its borders, its position, the presence of pericardial effusion can be correctly estimated. Likewise the study of the aorta, its size, presence or absence of aneurysm, deposits of atheromatous plaques in its walls, has become a conclusive one.

It is to-day practically an admitted fact that percussion, even in the hands of the most expert, cannot map out the cardiac borders. The overlying bony thorax, pleura, and lungs make it exceedingly difficult. In emphysema, when the heart is concealed by lungs of almost leathery hardness, it is entirely out of the question to outline its borders. I do not wish to imply that the Roentgen examination is the only method of diagnosis of cardiac diseases. It acts only as above mentioned, in ascertaining the size of the heart and in mapping out its contour. As the ultimate conclusion rests upon the function of the heart, capacity for work, etc., it is self-implied that all methods are but an aid to the final clinical tests.

Size: With the aid of the teleroentgenograph the actual size of the heart is correctly estimated. The exposure is taken with parallel rays at a distance of six feet so that distortion of the size of the heart is eliminated. The size of the heart varies in the normal state first according to the status of the individual. The status asthenicus has the long, narrow heart, the so-called drop-heart. The aorta is long and narrow, and the heart is situated low, corresponding somewhat to the ptosed abdominal viscera which occur simultaneously in these patients. The *status sthenicus*, or the broad-chested individual, shows more of a transverse heart. The size also varies according to the size of the individual, age, sex, occupation, and with respiration. In estimating the size of the heart in its normal state it has been found to bear a direct relation to the size of the thorax. This thoracic-cardiac ratio is as follows: the transverse diameter of the heart is equivalent to one-half the total diameter of the thorax, measured from the inner border of the ribs at the level of the highest point of the dome of the diaphragm (Fig. 7). The exposure is made in a dorsoventral posture during a moderate inspiration. In the *status asthenicus* it may be somewhat less than half. In the pathological state this ratio is disturbed, the heart increasing in size. The increase may be either to the right or to the left, depending on the type of the valvular lesion present. Normally the position of the heart is such that a perpendicular line drawn at the center of the spine will bisect the heart two-thirds to the left and one-third to the right of the median line. In other words, the ratio of the distance to the left border as measured from the bisecting tangent at the mid-spine to the right border is as two to one. This ratio is disturbed

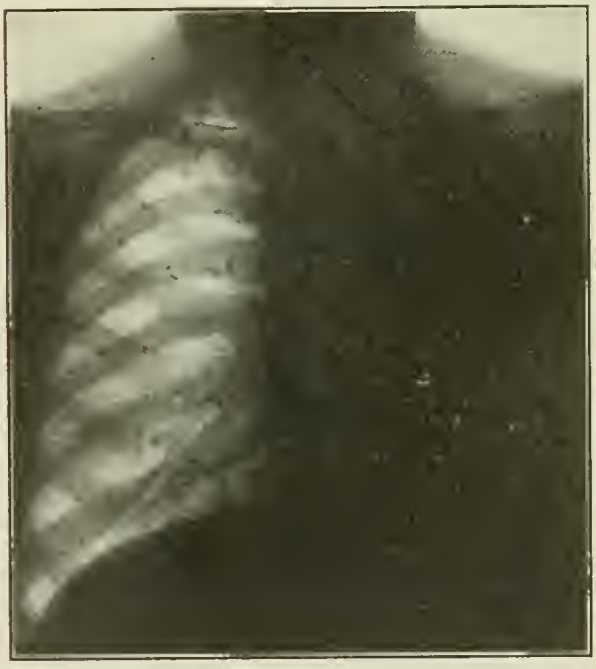

Fig. 12.—Extensive fibrosis of left lung with retraction of the heart, mediastinal contents, trachea, etc., all to the left so that none of these can be distinguished. Apex beat at mid-axillary line. Note compensatory emphysema of right lung. Also calcified healed tubercles scattered throughout right upper lobe. This process expresses a final stage in the healing of pulmonary tuberculosis. Hemorrhages date back 20 years. The patient is now apparently in good health well nourished, and attends to daily work; his only complaint is dyspnea on exertion.

according to the nature of the lesion, whether aortic or mitral.

Shape: The outline of the heart in disease, grosly considered, assumes two distinct shapes, one a spherical, the other an oval. The first occurs in

mitral lesion, and the second in aortic. In a mitral stenosis the left auricle is dilated. Therefore the left auriculopulmonic curve is seen to bulge while the aortic arch recedes. The size of the heart does not change, as the left ventricle does not hypertrophy in this disease. Later, however, with the enlargement of the right heart there will be an increase in size, the maximum deviation being to the right. The heart will take on a more spherical appearance, due to the enlargement of the right ventricle and auricle.

In mitral insufficiency (Fig. 8) the left ventricle enlarges also, resulting in a greater increase in the size of the heart, preserving, however, the spherical appearance.

In aortic lesions (Fig. 9) the aortic arch becomes widened. The auriculopulmonic curve is more accentuated. There is a very marked increase in the size of the left ventricle, the left border extending outward toward the left. The heart takes on an oval shape. The ventricular as well as the aortic pulsations are violent.

Pericardial effusion causes an increase in the size of the heart which takes on a triangular appearance with the base of the triangle below, and a broadened apex above. The normal outline totally disappears. The cardiac pulsations are not seen. A very faint wave may be noticed at its borders.

Aneurysm: Aortic aneurysm (Fig. 10) gives a very characteristic shadow. A sharply rounded pulsating mass is seen continuous with the aorta. This may spring from any portion, from the ascending, transverse arch, or descending aorta, or may involve them all simultaneously. It is distinguished from lung tumors, such as sarcomata, by its expansile pulsations. A lung tumor, if adjoining the aorta, may also be seen pulsating. This is, however, an impulse from contact and not expansile. The most dangerous aneurysms are those involving the transverse arch. Such a one may be very small and yet cause death in a short time due to asphyxia from the pressure on the trachea. This is the so-called aneurysm of symptoms with no physical signs. Those involving the ascending aorta are the least dangerous. Such aneurysm may assume an immense size and give physical signs of bruit, thrill, and musical murmurs, but will give few symptoms.

It is needless to say that in aneurysms the *x*-ray diagnosis is conclusive. One could hardly rely on the clinical interpretation alone even if symptoms were plentiful. A *pulsus paradoxus* or diversity in the blood pressure of the two brachials may well be due to other causes of mediastinal pressure, such as tumors. Aortitis, such as occurs in lues, is recognized best by Roentgen examination. Calcareous plaques are often seen in the coats of the aorta.

Conclusion.—I have attempted in this short résumé to point out some of the most important data in the Roentgen diagnosis of chest lesions. Attention must, however, be called to the fact that while in some instances the Roentgen diagnosis is conclusive, in others it is but corroborative, and no conclusion can be reached without the aid of clinical manifestations. It is for this reason that the roentgenologist must embody clinical acumen, and it behooves the clinician as well to familiarize himself with the Roentgen appearance of pathological states. It is only thus that we can reach the highest goal to serve our patients best.

A MENTALLY DEFICIENT CHILD WITH A PROTRACTED ELEVATION OF TEMPERATURE.*

By GEO. D. WOLF, M.D.,

NEW YORK.

ASSISTANT OTOLARYNGOLOGIST, HARLEM HOSPITAL; ASSISTANT OPHTHALMOLOGIST, MT. SINAI HOSPITAL, O.P.D.

THE following case presents several points of interest which may make it worthy of a brief report.

Family History.—P. E.—Male, aged 19 months; first child. Father and mother first cousins. Tuberculosis, syphilis, alcoholism, rheumatism, neurosis, or insanity, all negative. Wassermann test of both parents negative.

Past History.—Child was born at 9 months gestation; delivered by myself with low forceps with comparative ease after a protracted labor of about eighteen hours. Weighed 8 pounds. The following abnormalities were present: six fingers and six toes on each of the extremities; contraction of left small, ring, and middle fingers, and about two weeks after birth a bilateral inguinal hernia was noticed.

After two months breast feeding, the mother was advised in one of the city clinics to put the child on a bottle.

I saw this patient again at the age of three months when there was some difficulty in feeding. At this time the mother noticed that the child kept its mouth wide open all the time, failed to gain in weight, vomited after each feeding, and when the bottle was in his mouth the child seemed to be unable to take it well because of difficulty in breathing due to nasal obstruction. Adenectomy was advised then but the operation was refused. The child then passed from my observation until May 8, 1919. I then elicited the history that the patient had had diphtheria at four months and pneumonia when one year old. At this time the following complaints were presented:

1. Since he had diphtheria (almost 15 months previously) he has had a continuous temperature; it would sometimes be higher in the morning and sometimes in the evening, and apparently was not influenced by the condition of the bowels or diet or medication or

* Report presented before the Bronx County Medical Society meeting, June 25, 1919.

drugs which were prescribed by a number of physicians as well as in various clinics.

2. Constipation necessitating the daily administration of milk of magnesia and very often supplemented with a soap-suds enema.

3. At the age of four or five months the child did

Fig. 1.—Showing the habitus of the patient.

not follow objects and he was thought to be blind. He did not make any attempt to sit or stand. Coughed and gagged persistently; was fretful and scared at any noise; but had no convulsions nor tremors (tetany). His appetite was good, and he slept well, and gained in weight steadily. The first tooth appeared at about six and a half months.

Physical Examination.—Male child, fairly well developed in regard to height and weight, looks his age; weight twenty-one pounds.

Skin dry and pale; subcutaneous tissue boggy, but does not pit on pressure. Hair dry and abundant. Head

Fig. 2.—Showing intracranial changes due to pressure.

somewhat large for body, anterior fontanelle open but there is no bulging nor craniotabes. Circumference 50 (normal 45 cm.) Eyes, examined by Dr. J. Wolff on April 30, 1919, showed the following: Convergent strabismus of the right eye, and marked incoordination of the movements of the eyeballs. There was no optic atrophy and no optic neuritis.

Examination of the ears is negative.

The nose was somewhat flat bridged; there was a mucopurulent discharge from nostrils.

The mouth is wide open, tongue protruding, palate high, almost V-shaped, gums spongy and bleed easily. Fourteen teeth are present but all decayed. The pha-

Fig. 3.—Showing intracranial changes resulting from pressure.

rynx is filled with mucopurulent discharge; tonsils hypertrophied.

No Harrison grove on the chest and no beading of ribs noticed. Examination of the lungs is negative except crackling râles at both bases. Heart negative.

The abdomen is large and pendulous, tympanitic. No ventral or inguinal hernia. Spleen and liver not felt.

The fingers are thick and short; those on the left hand are contracted. The lymphnodes—cervical, inguinal, and axillary are palpable.

The mentality is almost nil; the child does not recognize anyone, does not respond to call except that he becomes frightened when spoken to; is not attracted by

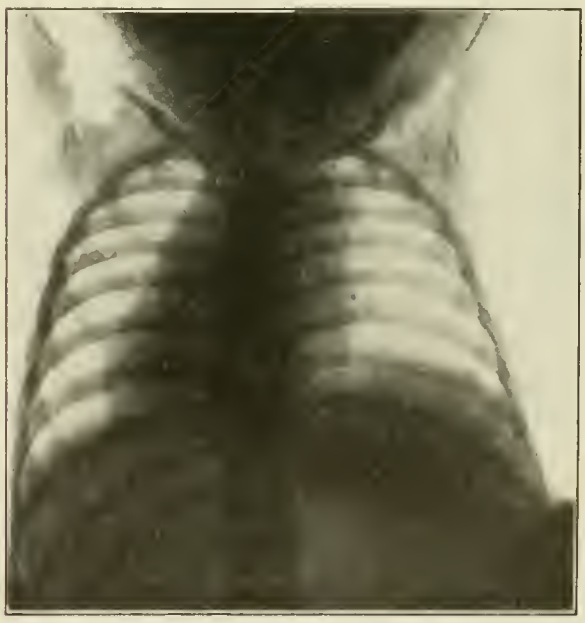

Fig. 4.—Enlarged suhsternal shadow.

light or color. Temperature 101.5°; respiration 22; pulse 90.

The urine is straw color, cloudy, strongly alkaline, odor strongly ammoniacal; microscopically shows amorphous material, no pus cells or casts; albumin faint trace, sugar negative.

The *x*-ray examination by Dr. E. Fox shows:

Chest: Very large substernal shadow, most probably due to enlarged and persistent thymus.

Feet: Accessory set of phalanges on the lateral aspect of each foot. No deformity of the 5th metatarsal.

Hands: Accessory set of phalanges and bifurcation and thickening of the 5th metacarpal on the right hand.

Fig. 5.—Polydactylism and contracture of fingers.

Accessory set of phalanges, but 5th metacarpal normal in the left.

Knees: Normal as regards centers of ossification; epiphyseal line normal in width and contour; diaphyses normal.

Skull: This region shows the most pronounced changes: (1) Extreme thinning of both inner and outer tablet of skull. (2) Large, open slightly bulging anterior fontanelle. (3) Widening of suture between frontal and parietal. (4) Digital depressions in the posterior fossa. (5) Obscuring of the basal landmarks of the skull. (6) Bulging of the frontal bone. (7) Round configuration of the head. All these pressure symptoms may be caused by a hydrocephalus. The possibility of a tumor at the base, anteriorly, must be kept in mind.

Conclusions: (1) Bones negative for nutritional disturbances such as rickets or scurvy. (2) Enlarged substernal shadow. (3) Evidences of increased intracranial pressure.

Subsequent History.—Since the mother appeared more perturbed over the child's temperature than over his mentality, and as she also had the notion that the former had a detrimental effect on the latter, a careful search for etiology of his temperature was made. I kept the child under observation for two weeks. During this time the temperature varied from 100.3° to 103°, sometimes higher in the morning and sometimes in the evening. Antipyretics had no effect. The von Pirquet test, the smear for malaria, and the *x*-ray for bronchial glandular enlargement and sinusitis were all negative. On account of the nasopharyngeal mucopurulent discharge the diagnosis of a chronic tonsillo-adenoid infection was tentatively made and removal of both was decided on, which I performed on May 22 under general anesthesia.

On the morning of the operation the temperature of the patient was 103.2°. The same afternoon after operation the temperature went down to 99° and later to normal and remained normal until June 14, four weeks, when the same fluctuating temperature reappeared.

In searching for the cause of the mental deficiency the following were considered:

1. Eclamptic or epileptic: While this in itself as a cause is doubtful in this case there is no history of convulsions.

2. Traumatic: Outside of the forceps delivery no other trauma known; but although there were no immediate effects noticed this cannot absolutely be disregarded.

3. Syphilitic: The absence of any of the signs of hereditary lues and the negative Wassermann in both parents exclude this condition with fair certainty.

4. Amaurotic family idiocy: Excluded on the basis of examination of fundi.

5. Alcoholism: Neither of the parents is alcoholic.

6. Asphyxia: None at birth.

7. Place in family: Both parents young and of about the same age.

8. Mongolian imbecility: This child certainly does not appear to be of this type.

9. Rickets: After the first glance at the patient one is certainly tempted to say rachitis, but since the cardinal symptoms of this disease are absent, and particularly because the *x*-ray shows no bony changes, this condition may be just given an honorable mention.

Having eliminated several possible etiological factors we are left with a limited number for differentiation.

1. Encephalitis: Inflammatory idiocy.

2. Consanguinity: Denied by many authorities to be a factor in idiocy.

3. Status lymphaticus: The only evidence in favor of this condition is the marked substernal shadow shown by the *x*-ray. Clinically there is nothing to account for it and there is no history of convulsion so often present in this condition. Furthermore, the child stood the anesthetic pretty well.

4. Chronic internal hydrocephalus (of the primary type): Against it, one cannot feel the separated sutures. The anterior fontanelle, though open, is small and is not bulging. The absence of the peculiar aspect of the eyes (convergent strabismus in this case followed an attack of diphtheria); the child withstood an attack of diphtheria pneumonia and a persistent long temperature. For it, findings of the *x*-ray.

5. Last, but not least, cretinism: There are certainly present a number of features reminding one of this—short thick fingers, boggy subcutaneous tissue, facial expression, protruding tongue, low forehead, short neck, decayed teeth, large pendulous abdomen, constipation, etc.

I have kept the patient on thyroid from May 26 to June 12, starting with ½ grain daily dose and

Fig. 6.—Polydactylism of the toes.

increasing to 1½. On June 14 the temperature went up again and I thought perhaps the increased amount of thyroid had something to do with it and I stopped for four days and resumed same on June 18.

The mother claims that the child recognizes his parents now, whereas he did not before; plays now a great deal more and is attracted by toys.

Subjectively the pallor of his face changed to a pinkish one, he perspired more freely, and gained three pounds in three weeks under the home condition of diet and surroundings.

Conclusion.—Whether we are dealing here with a primary cortical idiocy or one due to disturbances of one or more internal secretion glands or a combination of both, and whether the prolonged temperature had any relation to the mental condition or was due to presumptive infected tonsils and adenoids, is open to discussion.

641 Prospect Avenue.

THE TREATMENT OF EMPYEMA IN THE ARMY.

By CONRAD GEORG, JR., Captain M.C., U.S.A.,

AND

JOSEPH T. O'NEILL, Lieutenant M.C., U.S.A.

ANN ARBOR, MICH.

A GREAT opportunity for the comprehensive study of empyema has presented itself to the Medical Department of the Army during the great war. Empyema often occurred as a complication or a sequel to the numerous cases of bronchopneumonia which followed the measles epidemic at the various cantonments of this country. Furthermore, the widespread epidemic of influenza in the fall of 1918 provided many cases in addition to those that occurred as a sequel to the gunshot wounds of the chest in the war-zone.

These cases of empyema in the cantonments differed from those that we ordinarily observe in civil life because they frequently were the primary disease and not secondary to pneumonia. The most common types of acute respiratory infections observed in the cantonments were the hemolytic streptococcus and the pneumococcus. The mortality due to hemolytic streptococcus was as high as 50 per cent. in some of our camps. This may have been due in part to the exhaustion of our troops as a result of the severe physical strain which they had to endure while undergoing the intensive training necessary for foreign military service and of the overcrowding in tents and barracks. As a result their resistance to acute infections was low.

The virulence of the germ had considerable influence upon the rapidity of the progress of the disease in the different epidemics. Well pronounced cases of empyema were found to develop within two to four days after the onset of the illness. At autopsies upon cases of empyema held at the base hospital at Camp Wadsworth we observed that the disease was often the result of a perforation of a subpleural pulmonary abscess. During the early stage of the disease the fluid may be only slightly turbid or sanguinolent. This is particularly true in the case of infection with the streptococcus hemolyticus. There are often small pus collections around the bronchi in the parenchyma of the lung. It was found that cases of empyema due to the streptococcus hemolyticus were much more serious than those due to the pneumococcus. At Camp Jackson the mortality of empyema after bronchopneumonia was higher than when it followed lobar pneumonia.

At Camp Zachary Taylor one hundred and nine cases of pneumonia developed within a month's time from the middle of December, 1917, until the middle of January, 1918. Almost fifty per cent. of these cases had empyema also. There were fifteen deaths out of eighteen of the most virulent cases. The chest often filled with pus within twenty-four hours after the *x*-ray had demonstrated that there was no fluid present. Twenty patients out of eighty-six died of the disease. Rib resection was found to be a dangerous operation in many cases. Suction drainage gave the best results. In several cases collapse followed an exploratory puncture and there was one sudden death which was believed to be due to a vagus sympathetic inflex. There were no serious symptoms following aspiration when a preliminary injection of a 0.5 per cent. solution of cocaine was used and the pus withdrawn through the same needle. The sudden withdrawal of a large quantity of fluid resulted in symptoms of collapse twenty-four hours after aspiration.

At Fort Riley empyema occurred in 21 per cent. of 900 cases of pneumonia. Early operation was followed by a high mortality which was much reduced later on by resorting to aspiration and intrapleural lavage. Diederich reports that at Camp Pike the results following the trocarcannula method of treatment were better than those following rib resection. The mortality in 61 cases treated by the former method was 11.47 per cent., whereas, it was 47.6 per cent. in 63 cases treated by rib resection. The mortality was only 7.05 per cent. in a series of 95 cases treated by the trocarcannula method. At Camp Merritt of 181 pneumonia patients 81 had fluid in the chest and of these 56 had a purulent pleural exudate. Hemolytic streptococci were found in 51.9 per cent. of the pneumococcus sputa, 53.7 per cent. of the pleural exudates, and 70.4 per cent. of the purulent pleural fluids. Thirty-four per cent. of the pneumococcus pneumonias were complicated by chest fluid and 25 per cent. by empyema; 26.3 per cent. of pneumococcus and hemolytic streptococcus pneumonias were complicated by chest fluid and 24.9 per cent. by empyema; 15 per cent. of pneumococcus and nonhemolytic streptococcus pneumonias were associated with pleural fluid and 7.5 per cent. with empyema; 26 per cent. of all pneumonias in which pneumococci were found had chest fluid, and 20 per cent. had empyema. Hemolytic streptococcus pneumonia was complicated in 37.3 per cent. of the cases by chest fluid and in 25.4 per cent. by empyema.

At Camp Lewis, Major Fulton reported upon 57 cases of empyema and found that 50 per cent. were due to the streptococcus, 21 per cent. to the pneumococcus and 20 per cent. to the combined pneumococcus and streptococcus. The mortality was 22.8 per cent. The form of empyema which occurred at this camp was a very virulent type. Resection of the ribs was followed by disastrous results. Its mortality was high and the convalescence of those cases which recovered was much prolonged.

The experience acquired by army surgeons in

the treatment of empyema has shown that it is dangerous to resort to radical operations during the active stage of pneumonia on account of the risk of pneumothorax. Aspiration of the fluid contents of the pleural cavity has been found to be the only safe procedure during this stage of the disease. It may be repeated whenever the fluid accumulates in a sufficient quantity to exert dangerous pressure upon the intrathoracic organs. The pathology of acute empyema is now better understood as a result of this experience. In the early stages of this disease there is an acute infection characterized by chills, fever, and the formation of an exudate in the pleural cavity. At this period the fluid usually occupies the entire pleural cavity and there are no adhesions limiting its distribution. If an opening is now made in the chest wall by intercostal thoracotomy or by resection of a rib the patient will suffer not only from the shock of the operation and the rapid absorption of toxins through the opened vessels but also from pneumothorax. A positive pressure of atmospheric air equivalent to fifteen pounds to the square inch has been substituted for the normal negative pressure which exists around the lung. This results in the collapse of the affected lung and interferes with the normal exchange of gases during respiration. In cases of pneumothorax it has been observed that during inspiration the mediastinum, including the heart and large blood-vessels, is pushed toward the unopened side by the pressure of the outside air and during expiration the mediastinum returns to its former position or is pushed further outward. This fluttering of the mediastinum results in an incomplete distention of the healthy lung during inspiration and its insufficient collapse during expiration. In this manner an excessive amount of carbonic acid is retained in the blood which results in dyspnea, and the irritation of the circulatory center which is thus induced results in an increase in the volume of blood in the collapsed lung. The function of the respiration soon proves to be inadequate and the patient dies from asphyxiation from lack of oxygen. After adhesions have formed between the pleura and lung the treatment of empyema is not attended with as much danger of pneumothorax as during the acute stage of the disease.

The technique employed in the treatment of empyema at General Hospital No. 28, located at Fort Sheridan, Illinois, is as follows: The position of the pus in the pleural cavity is first determined by the use of the *x*-rays, physical examination, and exploratory puncture, and the thoracotomy is performed in the most dependent part of the empyemic cavity. Under local anesthesia a trocar and cannula is passed through the middle of the intercostal space into the cavity to avoid the intercostal vessels and nerve. A finger is placed over the end of the cannula as soon as the trocar is withdrawn to prevent the entrance of air into the pleural cavity. A rubber catheter is then passed through the cannula into the chest cavity and the cannula removed and at the same time a clamp is applied to the tube after the pus is evacuated. Aspiration of the pus is continued by means of a half-ounce bulb urethral syringe. The cavity is washed out with Dakin's solution until it returns clear. A forceps is used to compress the tube when the syringe is not connected with it so as to avoid pneumothorax. Twenty to sixty c.c. of Dakin's solution are injected into the cavity after it has been properly cleansed. Small amounts of this solution are injected into the cavity every two or three hours. This treatment is continued until the fibrous exudate has been dissolved and the pus has become liquid and mucoid in character. When this stage of the disease is reached the process of healing of the cavity generally becomes stationary. The smears show a low bacterial count but the wound fails to heal. At this time a two per cent. dilution of liquor formaldehyde in glycerine is injected into the cavity once daily after it has been cleansed with Dakin's solution. The amount of formaldehyde solution which is used varies from 3 to 40 c.c., according to the size of the cavity. This treatment is sometimes followed by a reaction characterized by a headache, rise of temperature, and a burning sensation in the cavity. There is also an increase in the amount of fluid during the first twenty-four hours, but this is soon absorbed and adhesions form, thus closing off the cavity. In a series of 50 cases under this treatment there were only two deaths, one due to infection with the *Streptococcus hemolyticus* and the other due to a general miliary tuberculosis. The remainder have recovered with an average disability of 12 to 15 per cent. The histories of a few of our cases are added to illustrate the good results of this treatment.

Case I.—A private aged 20, admitted to General Hospital No. 23, December 13, 1918. He had influenza and pneumonia in October and was operated for empyema November 13, by a rib resection. At the time of admission a tube was inserted into the old sinus and negative pressure used with Dakin irrigation. Culture of the fluid showed a pneumococcus infection.

January 8, 1919, the general condition was poor and the hands, face, and feet were swollen. Right apex not retracted, percussion clear, no constant râles. same findings posteriorly below the sixth rib. Grocco sign on left side. Heart normal. Probably retained pus in the right pleura.

January 14, 1919, the patient has spasms of coughing and tastes the Dakin solution when he is irrigated, indicating that there is a bronchus communicating with the empyema cavity.

January 22, the *x*-ray report states: "Left lung appears normal. Marked increase in density in the upper and middle lobe of right lung. Large empyema cavity extending up from the level of the diaphragm to the apex of the chest. Some aeration of the lower lobe. February 12, re-examination shows marked improvement in upper and middle right lobes, there being almost perfect aeration. Area of marked density extending from the level of the sixth rib down to the eighth. Adhesions right costophrenic angle. This area of increased density appears to be due to thickened pleura of the much contracted empyema cavity."

February 22, wound discharging profusely. Dakin tube inserted through sinus and about thirty c.c of greenish-yellow pus removed. Patient irrigated every three hours with Dakin's solution.

March 10, daily irrigations with Dakin's solution and 2 per cent. formalin glycerin solution. Smear counts low. Cavity holds only about ten c.c. Tube removed following injection of five c.c. of 2 per cent. formalin glycerin. Dressing applied and wound will be allowed to heal spontaneously.

May 25, patient has entirely recovered and has been given a disability of 12 per cent.

Case II.—A private aged 19, admitted to General Hospital No. 28, December 20, 1918. On November 17, a thoracotomy had been performed for empyema

following pneumonia under local anesthesia and a large amount of thick pus was evacuated.

December 20, tube inserted through old sinus and negative pressure with Dakin irrigation was used. Pneumococcus infection.

January 23, 1919, the *x*-ray report states: "Left chest compensatory emphysema. Right chest shows thickened pleura at the base extending up to the level of the sixth rib. Upper lobe of lung well aerated. Lower and middle lobes show partial aeration. Empyema cavity extends from the level of the sixth rib down to the base."

February 15, general condition good. Patient has very thick greenish yellow pus in irrigations. Abscess in skin around the tube. Expansion of right side very poor. Percussion over anterior portion of chest shows some dulness over upper and middle lobes with decrease of breath sounds. Posterior dulness throughout with extreme flatness in right lower lobe. There is an area of pneumothorax in right lower lobe from anterior axillary line to a point one inch posterior to posterior axillary line.

March 10, general condition much improved, character of pus has changed, becoming very thin. Daily injections of two per cent. formalin-glycerin solution. Smear count low.

March 25, progress favorable, cavity small, holds about 30 c.c.

April 8, smear count low, fluid very thin. Tube removed following injection of two per cent. formalin-glycerin solution.

April 30, sinus healed, patient in good condition. Breath sounds are audible over entire right chest. 15 per cent. disability.

CASE III.—A private aged 22, admitted to General Hospital No. 28, December 3, 1918. Patient had influenza October 12, and was delirious for one week. He was operated upon November 7, for empyema with drainage of several pints of pus within the next few days. Tube removed in two weeks. Upon admission it was observed that the affected side was flat and depressed throughout and contracted. Dulness and diminished breath sounds were noticed over the lower two-thirds of the left lung. Negative pressure and Dakin treatment was employed.

December 23, the *x*-ray report states: "Heart shadow is vertical, reduced in size and displaced to the right. The left lung with the exception of the apex is almost opaque to the *x*-ray. The left side of the chest is diminished in size and the contour is irregular. The right lung shows a marked peri-bronchial thickening throughout with numerous small circular areas of increased density in the hilus. The general clouding of the right side is apparently due to a pneumonitis."

Jan. 23, 1919, *x*-ray report: "Left lung shows an increased density in the upper and lower lobe due to a thickened pleura and a congestion of the tissues. Empyema cavity extends from the fifth rib to the base of the lung on the left side. The right lung is fairly well aerated." After the use of Dakin's solution he had a severe respiratory spasm and it was six or seven hours before normal respiration returned.

February 27, small amounts of Dakin's solution are now being used. The patient has had no violent paroxysms of coughing and much improvement is noted.

March 16, general condition is much improved. The Dakin tube was removed following the injection of five c.c of two per cent. formalin-glycerin. Cavity holds only about 20 c.c.

May 28, patient has made an uninterrupted recovery and has been discharged with a disability of fifteen per cent.

1022 FOREST AVENUE.

The Endocrinic Fever Syndrome.—This phenomenon was discussed at a recent session of the Société médicale in Paris. In certain cases of fever of obscure nature or fever confounded with typhoid, etc., the disturbance of temperature may be of thyroid origin. In the cases quoted the thyroid was shown to be slightly inflamed. Menstrual or premenstrual fever is another example.—*Journal de médecine et de chirurgie pratiques.*

A CASE OF RETROVERSION WITH UNUSUAL SYMPTOMS.

BY LUCIUS FELIX HERZ, PH.B., M.D.,

NEW YORK

THE following is a report of a not uncommon condition which was, however, marked by peculiar symptoms which seem to make it worthy of a permanent record.

L. M. N., an unmarried woman of twenty-six, first consulted the writer in June, 1917. She complained chiefly of extreme weakness in the legs when standing upon her feet for more than five minutes at a time. She would be compelled to sit down or lean against some object, from sheer weakness, and found that this handicapped her in her profession. She also complained of dysmenorrhea, with passage of clots. The pain preceded the onset of menstruation by two days, and was often so severe as to confine her to bed. Both the weakness and dysmenorrhea were of five years' duration. Headache and backache were absent.

Physical examination of the heart, lungs, and spine was negative. The teeth were in rather poor condition. The tonsils were normal. Vaginal examination showed a third degree retroversion. The tubes and ovaries were normal. Conservative methods of treatment had been tried by other physicians without avail, and consisted of douches, tampons, and emmenagogues.

Operation was advised and was performed by the writer at Flower Hospital, on July 3, 1917. A curettage was first done, and then a Gilliam suspension. Some small ovarian cysts were punctured. Appendectomy was simultaneously performed. Convalescence was uneventful except for the need of catheterization, which led to a subsequent low grade cystitis. The patient left the hospital in ten days.

The cystitis responded gradually to urotropin and bladder irrigations. Cystoscopy by Dr. Henry Dawson Furniss revealed a very mild trigonitis, which he thought might readily be a focal infection from the teeth. An *x*-ray of the teeth revealed some abscessed roots. Attention to the teeth, and continuation of the previous treatment, with slight modification (irrigation with 1-10,000 silver nitrate in 3 per cent. boric acid) soon cleared up the bladder condition.

The dysmenorrhea disappeared very promptly. The menses were somewhat profuse for a few times. The feeling of weakness in the legs disappeared more gradually, but as the patient regained her strength after the operation, she soon overcame this former disability.

The entire condition may have been a neurosis, but I am reporting this case because the symptoms were so different from the classical ones due to retroversion, and nevertheless the retroversion lay at the root of her difficulties as proven by their disappearance after the condition of the uterus was made normal.

251 WEST FORTY-FIFTH STREET.

Systematized Nevi.—Luneau claims the existence of generalized nevi in which there are malformations of the skin, subcutaneous tissues, muscles, and bones. These multiple lesions are of a dystrophic nature and are evidently associated with some central nervous condition. The subjects have often become tuberculous in later years.—*Journal de médecine et de chirurgie pratiques.*

Hysterical Tumor?—Levison saw a woman of 38 who presented a syndrome suggestive alike of hysteria and tumor of the cord. The family and personal histories were good up to the time of the present malady which began two years before. The symptoms of hysteria were clavus, ovarian point, hemihypoesthesia, and concentric limitation of the visual field. Certain constant pains of a neuralgic character and other phenomena suggested a beginning tumor of the cord. Spondylitis was excluded by an *x*-ray examination and lues by a negative Wassermann.—*Hospitalstidende.*

New York, November 29, 1919.

THE GENERAL SYMPTOMS OF ULCERATING PULMONARY TUBERCULOSIS IN INFANTS.

THE general symptoms of ulcerating pulmonary tuberculosis in infants must complete the very limited and deceptive local symptomatology. The physical signs of a cavity in the lung are late in appearing if we except a fixed and persistent dullness over the apex; the remainder are hardly worthy of consideration, so little importance can be given them. The general symptoms do not in themselves allow the clinician to differentiate the serious ulcerating forms from the commonplace types of infantile tuberculosis, but they occasionally offer a clinical picture having a characteristic aspect.

Fever in infants with a pulmonary cavity is very inconstant and irregular. It may be high, remittent, or continued; there may be a subfebrile state with remissions and it can be truly said that all types of temperature may be indifferently met with. Very high pyrexia is due to the final acute meningeal episodes.

The cavity in infants does not, like that in adults, appear to be itself the cause of the pyrexia, and hectic fever does not occur in them. On the contrary, cases of extensive ulcerating pulmonary lesions in infants may be quite apyretic. That apyrexia is common in tuberculous babies is well known, but it is interesting to know that it also occurs when cavities are present. It is probably an indication of a weak general reaction which is also made evident by the slight intensity of tuberculin reaction in infants, The antireaction may be wanting in infants with a well advanced pulmonary tuberculosis, as is often the case in young children.

Besides these signs, which are rather the negative elements in the diagnosis of cavernous tuberculosis in infancy, there are other very important symptoms which arise in the digestive tract. These have been well studied by Barbier. Their habitual grouping should lead one to consider them as essentially the result of hepatic insufficiency, or better still, a multiglandular digestive insufficiency. Infants who present these symptoms have irregular stools, indicating an intestinal paresis, the intestine being no longer stimulated by its own or annexed glands. The feces are thick, massive, lacking in color, with a fatty appearance and with a stale or frankly fetid odor.

Triboulet's test gives the reactionary biliary deficit, while chemical analysis reveals a defective utilisation of fats. The putrid odor of the stools indicates pathological fermentation at the expense of the albuminoids. All these phenomena reveal a profound disturbance of the hepaticopancreatic function. Diarrhea may take the place of the irregular stools, especially toward the end of the process and the cachexia then makes rapid progress. Anemia is the fatal consequence of this digestive insufficiency. It is early in appearance and intense and may largely occupy the scene. A tumefaction of the liver and spleen which may accompany the anemia is interesting, but it is far from being usual.

THE HEIGHT OF THE PALATE IN RELATION TO CHRONIC OTITIS.

THE significance of the form of the face, more especially the height of the palate, has been observed frequently, with regard to the origin of chronic otitis. At an early date it was noticed that an abnormally high and narrow palate was often accompanied by adenoid growths in the nasopharyngeal sac. Twenty years or so ago heated discussions were carried on in Europe respecting the origin of the high and narrow form of palate. Recently the question has been investigated again by Dr. Hakan Nordlund of the Oto-Laryngological Clinic of the Carolinic Institute of Stockholm at the instigation of the chief physician of the institute, Professor Gunnar Holmgren. It was decided that the investigation should aim at discovering whether any connection could be discerned between the occurrence of chronic otitis and the existence of a high and narrow form of face as an expression thereof, a connection that Professor Holmgren deemed possible. The results of these investigations are published in Vol. I, parts 2 and 3 of *Acta Oto-Laryngologica*. The investigations were carried out with the greatest care and the following conclusions were reached. Leptoprosopia is an expression of a general contour of the facial structure of certain individuals, being a relative extension in height, but more especially a narrower form of face. The general contour that in certain more extreme forms is very noticeable at first sight, is found in 43.5 per cent. in the proportions of the face, nasal apertures, and the palate, and in 39.5 per cent either in the facial conditions as regards shape or that of the nasal apertures together with a high narrow palate. The high and narrow palate, hypsistaphylia, is the thoroughly characteristic indication of the leptoprosopic type. To an extremely high degree adenoid growths occur in company with a high and narrow palate, while the palatal index of height and breadth in persons not suffering from any disease of the nose or ear, nor any glandular hyperplasias, on an average is 42.56; the index in cases with adenoid

growths is 51.08. About 72 per cent. of those having glandular hyperplasias in the nasopharynx showed one or other symptom of or predisposition to diseases of the ear.

The palatal height and breadth index in cases of chronic otitis was considerably higher, 51.52, than in those sound of ear, 42.56. In healthy conscripts the average is 44.25, but in mixed polyclinical material, where chronic otitis is eliminated, 44.06, in chronic ostitis 46.44, thus plainly proving an evident tendency of the palate to adopt a stronger hypsistaphylic type, the more the elements that influence inflammation of the middle ear are present. The cause of this more frequent presence of chronic otitis in individuals having high palates is to be sought in the far greater prevalence of adenoid growths also because the high narrow palate is combined with a high and narrow nasopharyngeal sac, by which the palatal curtain has a more vertical position, and the levator veli palati in consequence has a far less energetic effect on the opening of the tubal orifice. In consequence of this the opening mechanism in swallowing is rendered far more difficult to function. In this way salpingitis and affections of the middle ear more easily arise. Nordlund thinks that in view of the injurious effects on the ears which, judging from the investigations, sooner or later are produced in individuals with high and narrow hard palates, operative measures are sometimes indicated. Moreover, from the standpoints of examination for military service, railway work, life insurance, and so on, he, the author, suggests that it may well be worth while to take into consideration such conditions. The subject seems one to which sufficient attention has not been paid and the question of how great disability may arise from the neglect of aggravated cases of high and narrow palate may be worth further study.

HEADACHE OF NASAL ORIGIN.

An increasing amount of attention has been paid during recent years to the etiology and treatment of pain in the head. It is obvious that if the true etiology of a headache be not known rational and therefore successful treatment cannot be prescribed. It is only in recent years that a careful study has been made of the etiology of head pains, and consequently it is only within that period that effectual treatment for relief has been practised. Headache is undoubtedly very often of nasal origin and the rapid progress of rhinology has made it possible to relieve a goodly proportion of head pains which but a short time ago would not have been cured for the simple reason that their cause had not been diagnosed.

Dr. William Wilson writing in the *Practitioner* for October, 1919, attributes the successful treatment of the neuralgic type of nasal headache largely to Sluder's work on what is now known as the "sphenopalatine ganglion neurosis" and to the use of the nasopharyngoscope. He tabulates the following as three practical points with respect to head pains of nasal origin: (1) Persistent pain may be due to closure of the ostium of a sinus, even when the sinus contains no pus or evidence of disease; this pain is due to absorption of air from the sinus being a "vacuum" headache. Cases are occasionally seen in which the maxillary antrum requires frequent inflation with air through a trocar; this cures the pain for some time. Wilson has seen the most acute pain in a frontal sinus cured by making a large permanent drain into the nostril though no pus was present at any time. (2) Emile Glas has applied the well-known fact that in unilateral middle-ear disease with mucus or pus in the tympanum, the vibrations of a tuning fork placed in the midline of the skull are heard chiefly on the diseased side; and has shown that, if the ears are normal, a similar transference of the vibrations is effected to the side of a diseased nasal sinus if the latter is present. This is a simple test that any physician, even one not acquainted with ultranasal technique, can perform. (3) If pain persists after opening and draining an empyema of the antrum, and no other sinus is involved, one should suspect malignant disease, even though the radiogram is negative.

Wilson gives a classification of headaches of nasal origin and he describes the varying pains dependent upon the different nasal regions affected. The periodicity of nasal headaches is somewhat remarkable; they are worse in the morning from ten o'clock and improve in the afternoon. Also it is worthy of note that when obstruction in the nasopharynx occurs chiefly from adenoids, there is no specially localized pain. This is, however, what might be expected, for the main trouble is a general obstruction to vascular and lymphatic exchange over the greater part of the cranial contents.

It is well that the attempt is now being made to trace headaches to their origin and not to treat them as if they were always due to the eyes or to stomach trouble. It has been asserted that headaches are more frequently the result of nasal affections or defects than of ophthalmic troubles, which, however, may be doubted. Nevertheless, the end of all investigation is to arrive at the truth, for it is only then that a rational treatment can be instituted.

HYPERTENSION IN TUBERCULOSIS.

Although tuberculosis is usually mentioned as one of the great factors in lowered blood pressure this should not blind us to the fact that increase of tension is often present in the individual case. Dr. Colbert has analyzed a number of these cases and publishes his results in the *Journal de médecine et de chirurgie pratiques* for September 25. He finds that in chronic pulmonary phthisis hypotension is the rule. The tension diminishes during an access of the disease, and when improvement sets in it increases again. With recovery the tension is within normal bounds. The author restricts his material by excluding subjects over 40 years of age and those whose tension is below 18 Pachon as a maximum. He finds increased tension due to various causes as forced feeding and renal complica-

tion. He further eliminates the association of tuberculosis with all hypertensive diseases, such as syphilis. Finally he insists that the cases must be or have been of the open bacillary type.

The old idea that a hypertensive tuberculous subject must have kidney disease is exploded by the author's finds. In 300 cases studied over an interval of four years he found 15 who appeared to have an idiopathic hypertension. Among these the maxima by Pachon's scale were 25-26 and the minima 10-11. The pulse was often very rapid just as in the hypotensive. In the hypertensive there is a natural tendency to hemoptysis. The general health in these cases is often surprisingly good, and it is not unlikely that the connection long known between recurrent hemoptysis and a good prognosis for life is associated with elevated blood pressure. Not all hemoptysis is of this type and the so-called congestive form seems most akin to it. At the time of the hemorrhage the patient has no fever and is not in the midst of an exacerbation of the disease. The author finds in his own material the same prognosis. When the tension is very high —20 Pachon, for example—it requires treatment. Nitroglycerin and emetine are valuable for reducing the tension promptly. After the hemorrhage has begun the treatment comprises rest, an intramuscular injection of emetine and revulsives.

A New Cutaneous Reaction in Tuberculosis.

During the present year Wildbolz published an account of a new tuberculosis reaction due to intradermic inoculation of a patient with his own urine. At a subsequent session of a local Swiss medical society reported in the *Revue médicale de la Suisse romande* (October, 1919, xxxix, 10) Guye discussed this reaction. He began with the statement that tuberculous urine is not known to contain an antigen. However, the experiments of Wildbolz appear to show that such an antigen does occur in that fluid. Tests with urine of normal subjects gave negative results, while the urine of tuberculous subjects invariably set up a local reaction at the point of injection which was sufficiently like that caused by tuberculin. When tuberculous subjects are injected with the urine of patients with infectious diseases other than tuberculosis, the reaction does not appear. Moreover after tuberculin has been used to provoke a reaction in the tuberculous subject, he no longer responds to the urine test. If after a positive intradermic urine inoculation, tuberculin is used in the vicinity, the point of the urine inoculation is once more activated. In short the chain of proof of the constancy of the reaction is nearly complete, although to obtain it the subject must have active, not latent tubercle. Guye, with another, now repeated the experiments of Wildbolz with 75 individuals and the discoverer supervised the work, thereby discounting claims of differences of technique. The urine must be concentrated to a tenth of its bulk, this requiring 20 minutes, and must be shown to be sterile by the negative result of inoculating certain media. The point of the needle must be within the corium. The results in every way confirmed the claims of Wildbolz.

Lung Abscess Following Tonsillectomy.

In England and America this operation has a wide vogue, especially in America. In some other countries, of which Holland is one, this intervention is much less popular and restricted to certain definite indications with full recognition of the possibility of serious accidents. Burger, a practitioner in Amsterdam, was therefore not surprised at a statement to the effect that in a large New York general hospital pulmonary abscess is a not uncommon sequela of the operation of excision of the tonsils (*Nederlandsch Tijdschrift voor Geneeskunde*, November 1, 1919, lxiii, 18). The mortality of a series of cases from mixed sources was 11 per cent. Following the files of the *Laryngoscope* and other periodicals, the Dutch author brings to light other cases reported by Richardson, Frank, Warthin, Christian, Wilson, Herrick, Dean, Robinson, McKentie, Lilienthal, Craig, Billings, and others. These cases were largely in children, and the operations were in many cases done under full narcosis. Every case cited was an American case. The favorite cause assigned was aspiration of material, infected or not, while in some cases septic embolism may have been responsible. An example of the latter seems to have been reported by Scruton. This unpleasant accident is not deemed inevitable, but due to faults of technique. It is fortunate that the mortality has not been greater while the incidence, considering the enormous vogue of the operation, is low. The indiscriminate performance of the operation should be condemned in view of the possibility of this mischance. The cases do not appear to be reported by the laryngologists, but by the internists and surgeons who treat or operate on the lung abscesses, and at times by the pathologists who make the autopsies.

An Old Time Medical Scold.

A recently published Paris thesis by Maitre, reviewed in the *Journal de médecine et de chirurgie pratiques* (October 25, 1919, xc, 20), is devoted to the life and activities of de la Mettrie, an XVIII century physician, contemporary of Astruc, who was a lifelong censor and critic of his profession. He died at the early age of 42. By his ceaseless attacks and strictures on his brethren he became one of the most disliked physicians in the history of medicine. Naturally he had nothing better to offer, so that his criticism was eminently destructive. He inveighed against the methods of teaching and alike against anything which savored of the commercial exploitation of patients. He was opposed to theory and made all possible capital out of mistaken diagnoses—for example that of a brilliant practitioner who inadvertently mistook an overfilled bladder for an abscess. Perhaps in imitation of Molière, he wrote a comedy against the profession called "The Charlatan Unmasked." In searching for a motive the author can only discover a natural bent toward sarcasm which naturally found its outlet in his medical environment. In regard to his character it seems to have been one of singular honesty and purity, with a natural goodness of heart. In addition to numerous technical papers he wrote largely on medicophilosophical subjects. According to the author, all of the latter publications

were superficial and hastily written. He had the correct idea of method, which should be based on observation and experiment, but he reached conclusions that were anything but sound. On the other hand some of his more technical writings have a certain value—for example, one on vertigo of stomach origin, which he identified and cured by appropriate diet.

News of the Week.

Rejection of Compulsory Health Insurance by the Medical Society of the State of New York.—A special meeting of the house of delegates to consider the report of the committee to study the subject of compulsory health insurance with special reference to its relation to the medical profession was held at Albany, November 22, with the president, Dr. Grant C. Madill of Ogdensburg in the chair. The constitution of the committee was as follows: Harvey R. Gaylord, *Chairman*, Buffalo; Grant C. Madill, incoming President, Ogdensburg; Thomas H. Halsted, retiring President, Syracuse; Joseph H. Hulett, President First District Branch, Middletown; Frederick C. Holden, President Second District Branch, Brooklyn; Luther Emerick, President Third District Branch, Saugerties; Thomas A. Rogers, President Fourth District Branch, Plattsburg; G. Massillon Lewis, President Fifth District Branch, Vernon; R. Paul Higgins, President Sixth District Branch, Cortland; John H. Pratt, President Seventh District Branch, Manchester; Albert T. Lytle, President Eighth District Branch, Buffalo; J. Richard Kevin, Chairman Committee on Legislation, Brooklyn; Henry L. Winter, Chairman Committee on Medical Economies, Cornwall; Arthur W. Booth, Member State Board of Medical Examiners, Elmira; George W. Kosmak, Chairman Committee on Legislation, Medical Society, County of New York. New York; John A. Lee, Chairman Committee on Legislation, Medical Society, County of Kings, Brooklyn; James F. Rooney, Chairman Committee on Legislation, Medical Society, County of Albany, Albany; Walter H. Kidder, Secretary Medical Society, County of Oswego, Oswego. The incoming President, Grant C. Madill, added to the committee Sigismund S. Goldwater, Medical Director Mt. Sinai Hospital, New York.

Dr. Harvey R. Gaylord, chairman of the committee, presented the following report, which was unanimously adopted:

Your committee would like to offer the following brief résumé of the subject of its study before stating its recommendations:

The essential components of all compulsory health insurance schemes are two: First, the provision of a cash indemnity during a relatively brief period of incapacity to labor due to illness; secondly, the provision to the insured and their dependents during a determinate time of socalled medical benefits which comprise medical, dental and nursing attendance, hospital and sanatorium accommodations, maternity attendance, drugs and all necessary medical and surgical supplies.

The proponents of this legislation rest their demand for the institution of this scheme in America upon two main allegations: First, that a very large amount of poverty is due to illness causing consequent unemployment and loss of income; secondly, that a vast amount of the population receives inadequate and insufficient medical attention, that is, that medical attendance is grossly deficient both as to quantity and quality.

With the general features of the measures proposed for the legislative enactment of the compulsory health insurance scheme in this State your committee will deal only in the briefest manner; the matter is familiar to you. It is proposed to establish an administrative machinery radiating downward from a division of the State Industrial Commission, composed of a certain number of commissioners appointed by the Governor, who in turn appoint a chief of the bureau of health insurance. Subordinate to the commission and acting under regulations made by the commission, function the boards of directors of the local funds, composed of three members elected by the employer members of the local fund, three elected by the employees and one additional elected by these six. All the affairs of the funds are administered locally by these boards of directors. Each local fund employs a medical officer who is permitted to practise and who is practically the medical supervisor of the administration of the benefits of the act. The medical profession is not represented upon any executive body under the proposed law, but is permitted to function solely through advisory committees, local and State. Its sole statutory representative has an administrative, not an executive function.

After consideration of the evidence put forward by the proponents of this legislation in support of their statement that a large proportion of the poor have been impoverished through unemployment caused by illness, your committee finds that none of this evidence is unimpugnable and that it rests largely upon a priori reasoning. The preponderance of evidence is against the fact that any considerable amount of impoverishment is caused by illness; moreover in those cases where impoverishment is caused by illness, it is due to the long enduring disability preceding death occurring in the chronic diseases, especially tuberculosis, chronic heart disease, cancer, chronic joint infections, renal and vascular disease, which cause a disability long exceeding the period of twenty-six weeks during which the insured is entitled to benefits under the scheme. The statistics of the Labor Bureau of New York State show that in the main disability from all causes including accidents, injury, and illness is the source of, on the average, only 5.7 per cent. of unemployment, about the same amount as that caused by weather conditions (5.6 per cent.) or a little less than half that caused by labor disputes (10.6 per cent.), or one-thirteenth that due to lack of work (74.6 per cent.). A survey entitled "Poverty in Baltimore and Its Causes; Study of Social Statistics in the City of Baltimore," by the Alliance of Charitable and Social Agencies, McCoy Hall, Baltimore, Maryland, November 15, 1918, gives strong evidence of the small part illness plays in the cause of poverty; moreover, it evidences strikingly the fact heretofore stated as to the relationship of prolonged disability not covered in any scheme for health insurance to the relatively few cases of impoverishment due to sickness. Your

committee find, therefore, that short illnesses causing ephemeral disability bear no relation to poverty; that where impoverishment is caused by illness it is in all instances due to long-continued disability; and that illness is but a very minor cause of unemployment as compared even to the conditions of the weather or labor disputes.

Your committee is unable to find any available evidence that will bear inspection proving that, in the main, medical attendance in this State is grossly deficient in quantity or grossly defective in quality. If these facts were true it is unable to satisfy itself that the people of this State would receive a larger and closer degree of medical attention where one physician may care for some two thousand or more patients as permitted under this scheme than they now receive where the proportion of physicians to population is about as one is to seven hundred and eighty. Moveover, your committee is satisfied that the quality of medical attention would no more be benefited in the United States than it has been in Germany, Austria, and Great Britain, by the conversion of medical practice from its present plan into an enormous scheme wherein the practitioner would be employed from year to year under contract, and in the final analysis subject to lay dictation as to means and methods of practice.

Your committee feels very strongly that the inquisitorial powers which would be conferred upon the State Industrial Commission and its agents, and upon the local boards of directors must be considered in its effect upon the public health, and especially as to the rôle it might assume in submerging and nullifying the activities of the present State Department of Health, which has played so large a part in the reduction of morbidity and mortality by means of preventive, not palliative, medicine.

There is no uncertainty about the evidence that the relative morbidity rate, mortality rate, infant mortality rate, and maternal mortality rate, has been much more materially reduced in the United States during the past twenty years than it has been in Germany and Austria where compulsory health insurance not alone, but the whole scheme, including invalidity and unemployment insurance and old age pensions, have been in force. It can, therefore, be seen that compulsory health insurance as such plays a very small part in the reduction of length and severity of illness and that on the whole it has been of extremely little value, medically, in those countries; while it has been the cause of a profound deterioration in medical service and medical morale. Even in England, where it has been in operation for a comparatively short time, it has proven so defective and ineffective for the purposes for which it was instituted that it is now proposed to inaugurate the plan of State medicine to supplant it.

Your committee, therefore, finds:

First: There is no necessity for the institution of a scheme covering the major portion of the population of the State providing for the institution of contract medical practice on a colossal scale in order to furnish medical attendance and other services.

Second: In those countries where this scheme has been in operation for many years, it has caused a deterioration in medical morale and medical service and its effect in this State would be the same, that is, a lessening in the quality of medical service.

Third: In comparison with those countries where this scheme has been in operation the United States shows a more marked reduction in mortality rate, both general and as affecting maternal and infantile mortality rates. Apparently the morbidity rate under the scheme has doubled instead of being diminished in Germany and Austria since the institution of the social insurance plan.

Fourth: There is danger of the scheme gradually undermining the functions so extremely valuable to the community at present subserved by the State Department of Health.

Fifth: Owing to the paucity of accurate and unimpeachable data collected by means of an unbiased investigation, your committee recommends that the Legislature of 1920 be requested to appropriate a sufficient sum of money for the use of the Health Department, and such other departments in association with it, as it requires, for the purpose of making a survey of the State of New York to determine the amount and character of illness in its economical relation to the commonwealth.

Sixth: If additional legislation is to be enacted, it should provide for a greater development of existing agencies for preventive medicine, together with the extension on a large scale of the present county and municipal functions for both preventive and remedial medicine, and it should make further provision for the inauguration of a more widely extended utilization of the present institutional clinical facilities for the diagnosis and treatment of disease, in order to facilitate the access of the entire population of the State to modern methods in the practice of medicine.

Your committee, therefore, recommends that the House of Delegates, and, through them, the Medical Society of the State of New York, unqualifiedly oppose the enactment by the Legislature of the State of New York of any law instituting a system of compulsory insurance against sickness, because of its menace to the public health of the State.

Guard Against Canadian Smallpox. — Vaccination against smallpox has been imposed by this county on all travelers from Toronto and its vicinity entering the United States ports of entry. The reason for this action is the prevalence of smallpox in those districts.

Medical Veterans Organize.—Forty physicians of Portland, Me., met on November 5 and organized the Medical Officers of the World War of Cumberland County.

Obituary Notes.—Dr. CHAUNCEY W. COURTRIGHT died at his home in Chicago, November 9, after an illness of nearly three years. He was born at Delaware Water Gap, N. J., in 1850. He was a member of the American Medical Association and a fellow of the American College of Surgeons.

Dr. FRANK O. SHERWIN died of Bright's disease at his home in Duluth, Minn., on October 24, aged 66 years. He was a graduate of Rush Medical College, Chicago, in 1881, for almost twenty years marine surgeon of the Port of Duluth, and for a time health commissioner of the city.

Dr. ABRAM CASE WILLIAMS, a graduate of Yale Medical School, in 1885, died after a brief illness at his home in Springfield, Mass., aged 50 years. He entered the medical department of the Second Regi-

ment in 1899 and retired from the service as Major in 1916.

Dr. PAUL W. ABELL of Charleton, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1893, died in a local hospital following an operation for gallstones, aged 53 years.

Dr. FRANCIS C. MURPHY of Boston dropped dead while making a professional visit, on November 2. He was a graduate of Harvard Medical School in 1886, and was 60 years of age.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, November 7, 1919.

The Training of the Tuberculous Sufferer.—Much is heard nowadays concerning tuberculosis, and the campaign against the disease in Great Britain, which was halted by the war, is now getting into operation again. At the Royal Institute of Public Health, Russell Square, London, a special course of lectures and demonstrations on tuberculosis are going on up to Dec. 18. They began on October 9, Dr. Halliday Sutherland giving the first lecture on the early diagnosis of tuberculosis. On October 30 Dr. Jane Walker, Medical Superintendent of the East Anglican and Maltings Farm Sanatorium, Mayland, Suffolk, gave an address dealing with the training of the tuberculous sufferer. Dr. Walker divided those suffering from pulmonary tuberculosis into three classes. Those with the disease in its incipient form but which had been arrested. She was of the opinion that provided a person was young, not over 22, and the disease was arrested, it did not constitute much of a handicap. Indeed, she was not sure but that in some ways it was an advantage, as it conferred a certain degree of immunity. There was no need for such persons to leave lucrative occupations, that is, if they took good care of themselves and did not lower their vitality by an indiscreet mode of life. Dr. Walker here made somewhat of a discussion by deprecating the value of the advice so frequently tendered to tuberculous individuals to leave their work in a town and seek some light occupation in the country. She declared that the light job in the country was a chimera, a figment of the brain. Work in the country almost invariably meant agricultural work, which implied the possession of a good deal of skill only gained by long experience, long hours, and arduous labor. Farming work was certainly not appropriate for the great majority of consumptives. The next class consisted of those whose disease was not arrested, but who as a rule did not suffer from the malady in an acute stage, and who went through life with the germs of tuberculosis more or less active in the system. Such persons were never quite well and yet sometimes lived to be fairly old and died from another disease. Those thus afflicted should not be advised to do ordinary industrial work. However, according to the views of the speaker founded on her own experience, the advice given as to the kind of work to be done by this class of consumptive depended largely on temperament. If a person was of a cheerful, optimistic, placid temperament he or she stood a much better chance than one of an irritable, worrying nature. Character counted for a great deal in the tuberculous subject. Still, if a man was over thirty, and a skilled textile worker, for instance, with a wife and family depending upon him, let him continue at his occupation. If he changed he might obtain healthier work, but if he were unused to it and did not earn nearly so much money, he would worry and the mental strain might affect him more adversely than his former less healthy employment.

Health Work in Wales.—The Ministry of Health has announced recently that in accordance with the expectations held out to Welsh members during the discussion on the Ministry of Health bill, arrangements have now been made to extend considerably the functions of the Welsh Board of Health. The work to be immediately transferred includes all the functions of the Housing Department of the Ministry of Health in Wales.

An Eight-Hour Day for Doctors.—It appears that the medical men of Brest have been demanding an eight-hour day. Dr. Cox, secretary to the British Medical Association, discussed recently with a press representative the possibility of adopting in England an eight-hour day for doctors, and said it was absurd to even think about it. He did not see how it could possibly be arranged in this country or any other. A regularized tour of duty for practitioners could only be carried out in any conceivable circumstance by a state medical service, and it seemed that the medical profession did not desire that.

A Trade Union for Nurses.—It has been stated that trained nurses in this country propose to form a professional union, to be registered under the Trade Union Act. In Great Britain the trained nurse is not nearly so well paid as in America. In many institutions nurses have long hours and meager remuneration. Technically speaking, in a way, the medical profession is a strong trades union. Unless a medical man is qualified according to the requirements of the General Medical Council, he cannot register, and without registration he cannot practice. This debars the unqualified man from practice. The trained nurse who has undergone a rigid training and whose qualification calls for a very considerable amount of time and skill has no such protection. Any one can wear the uniform of a nurse, and take fees without laying herself open to prosecution.

Students at Manchester University.—As mentioned in a previous letter, students are flocking in great numbers to the British universities. Oxford and Cambridge are full to overflowing and at both of these old universities there is a fair number of medical students. Neither Oxford nor Cambridge has ever been a medical center. Students of medicine spend only a year or two years of their medical student life at these schools, for the reason that they can obtain little clinical experience. They train for the most part at the London hospitals and go to Oxford and Cambridge for their examinations. On the other hand, the universities of the north, and especially those of Scotland, are renowned as medical schools. The number of students at Manchester University has greatly increased, and regis-

tration is not yet complete. Before the war some concern had been expressed at the falling off of medical students. At the present time there are nearly seven hundred in residence, of whom one hundred are women students. The departments of dentistry and pharmacy are also very full and it appears that there may be some difficulty in providing sufficient laboratory accommodation for the instruction of so many students in all these departments.

Dr. J. C. Meakins, formerly of McGill University, has been appointed to an important post in Edinburgh University. He is the first occupant of the Christison Chair of Therapeutics. He gave his inaugural lecture on October 23, the subject being "The Influence of Edinburgh on McGill University and American Medicine." Professor Meakins sketched the development of medical education in Canada during the eighteenth century. James McGill, the founder of McGill University, was born in Glasgow in 1744. He went to Canada and made a fortune. He made his home in Montreal, and when he died in 1813 it was found that he had willed the estate of Burnside and £10,000 to found an English-speaking university one of the colleges of which was to be called McGill College. The only active medical teaching body in Canada at the time was the Montreal Medical Institution, and this became the medical faculty of the new university. This institution was wholly composed of men from the Edinburgh medical school, who introduced into Canada the Edinburgh methods of medical teaching, and these methods for the most part have been continued up to the present day. It was through the efforts of Dr. Dawson, an Edinburgh graduate, that McGill was brought into prominence as a medical school. Since the time of Dr. Dawson it has become a tradition unconsciously that an Edinburgh graduate should be principal of the Montreal University. The recent appointment of Sir Auckland Geddes to the post is only a continuation of the tradition. As Professor Meakins pointed out, in the past hundred years there have been few exceptions to break a steady line of Edinburgh and McGill men occupying chairs at the McGill Medical School.

Amalgamation of the Post-Graduate Schemes in London.—The Post-Graduate Association has amalgamated with the Fellowship of Medicine. Meetings have been held and the resolution has been come to that these bodies should join and that the amalgamated body should be termed "The Fellowship of Medicine and Post-Graduate Medical Association." The committees have united and held their first meeting as one committee on October 24, when a program of future work was discussed and an executive committee appointed. The officers and committees of the former Post-Graduate Association will make their headquarters with the Fellowship of Medicine, which will be continued at the home of the Royal Society of Medicine. The present officers of the Fellowship have been asked to continue in office until the executive committee is able to report upon the future scheme of work. The officers are: President, Sir William Osler; Chairman of Executive Committee, Sir Humphry Rolleston; the Treasurer, Sir Arbuthnot Lane, and Hon. Secretaries, Sir J. Y. W. MacAlister, Mr. Philip Franklin and Mr. Herbert J. Paterson.

LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, Nov. 1, 1919.

Uterine Hemorrhage.—The subject for discussion at the fourth annual meeting of the Gynecological Society of Switzerland, which was held at Berne on Oct. 18 and 19 last, was functional uterine hemorrhages. Two reports on the subject were read, one by Prof. Meyer-Ruegg of Zurich, the second by Dr. C. Waegeli of Geneva. The first report is a long-drawn-out exposition of the subject, containing more theory than fact; the second is a very common-sense summary of the question, and I will give the writer's conclusions, which, as he states, are the only ones he is inclined to offer, given the present state of our knowledge of the pathogenesis and pathology of functional uterine hemorrhages.

It is sure that a certain number of uterine hemorrhages of either menorrhagic or metrorrhagic type, occurring without any anatomic lesion of the genital apparatus, are of purely functional origin. Among these are to be placed the hemorrhage of puberty, and the menopause, as well as the majority of those which have been looked upon as the consequence of endometritis or metritis.

The organ whose dysfunction most frequently causes uterine hemorrhage is the ovary, and here are to be found the elements upon which depends the uterine secretion, and consequently the soudce of the loss of blood as well. The internal secretion of the ovary itself cannot be denied, as too many clinical and laboratory experiments have conclusively shown that the ovary controls various physiological and pathological manifestations of the genital apparatus. Besides this preponderant part played by the ovary in the production of hemorrhage, it is probably that loss of blood can also be provoked by other glands of internal secretion, either directly or because a certain disequilibrium becomes established between them and the ovary. These anomalies exist, perhaps, by themselves, but they may be also secondary to some constitutional affection of a general kind, in which case they produce hemorrhage either by direct nervous influence on the uterine mucosa or its blood vessels, or by the intermediary of the ovary.

The most varied affections of the organism, such as acute infectious processes, tuberculosis, cardiac lesions, etc., as well as various conditions provoking a stasis in the pelvic vessels, are equally capable of causing functional uterine hemorrhages. The act either directly on the uterine mucosa by means of circulatory disturbances or, perhaps, also by the intermediary of the internal secretion. Finally, it is possible that certain uterine hemorrhages met with in some well characterized anatomical affections are *partially* functional in nature. Among these are to be placed hemorrhage from retroflexion or myomata, but for the present, at least, they cannot be regarded as purely functional, and this hypothesis should be completely rejected in the case of hemorrhage from submucous polypi and inflammatory lesions of the uterine adnexa.

Subcutaneous Emphysema.—Recent studies in France have demonstrated that two varieties of subcutaneous generalized emphysema exist in measles. The first variety is due to bronchopneu-

monia, whooping cought, laryngitis, or tuberculosis, and is not peculiar to measles *per se*, but rather to the complications of this infectious disease. The second variety arises during measles, undergoing a normal evolution, without pulmonary or any of the above-mentioned complications. The condition is uncommon, and occurs especially in children.

The emphysema is not accompanied by pneumothorax, and is, in fact, mild; the patient recovers rapidly, and I know of no fatal outcome. Although no necropsic verification has been made to date, it is probable that the process is due to rupture of the pulmonary alveolæ. The emphysema just infiltrates the lung between the lobules, and then extends into the mediastinum, and then subcutaneously or into an ulceration of the larynx seated in the ventricle of the larynx. The air penetrating by effraction into the periladyngeal, cervical, facial, thoracic, and abdominal connective tissue, following paroxysms of coughing, results in the production of the emphysema.

1. Silent Renal Calculi.—Dr. Edward L. Young, Jr., in the hope of elucidating certain questions concerning so-called silent renal calculi—those which give few if any symptoms, and which are discovered by *x*-ray when some other lesion is being studied, or by the life insurance examiner who finds albumin or a few pus cells—went through the literature of the last few years, and looked over nearly 4,000 autopsies done at the Massachusetts General Hospital since 1896. Where stones were found he noted the gross and microscopic condition of the kidneys and correlated the data with the clinical symptoms and urinary findings. He found that in the nearly 4,000 autopsies studied 45 cases were found of stones in the kidney or ureter, or both. Of these there was only one case with a completely negative history and urinary findings, and normal kidney macroscopically and microscopically; there were four cases without symptoms and with negative urine; six cases without damage to be demonstrated at autopsy; and fifteen cases where the damage was too slight to compromise the integrity of the kidney. Two cases with stones in calyces known to have been present for at least six or seven years, who had had repeated attacks of renal colic, showed one a normal and the other an essentially normal kidney. Stones in the ureter more surely do kidney damage than stones in the pelvis or calyx, and a small stone, if arrested in the ureter, may do as much damage as a large one. Stones in the calyces can cause as much damage as stones in the pelvis. Pus can be present during life without any evidence of infection or damage at autopsy, so that the presence of infection as well as of pus is necessary before important kidney damage is proved to be present. The presence of a stone of any size in ureter, pelvis, or calyx may cause slight tissue changes, characterized microscopically as "slight increase of interstitial tissue," "slight arteriosclerosis," or "slight atrophy of venal elements," but these lesions are not constant, and apparently are of little if any account so far as the work of the kidney is concerned; aside from this there is no damage done the kidney by the stone as such. But the vast majority of renal or ureteral stones do at some time or other cause some obstruction and always invite infection, and accordingly are sources of danger to the individual. In any given case without infection or other evidence of kidney damage a calculus may be left alone until it is passed, until pain forces an operation, until evidence of infection and damage begin, or until it is shown to be increasing in size so that a pyelotomy becomes more difficult. In the case of a ureter stone, if in spite of cystoscopic manipulation it has ceased to make progress, it should be removed after remaining stationary for only a relatively short time, in spite of possible lack of symptoms, as the kidney almost certainly will be badly damaged.

1. The Significance of Vascular Changes in the So-called Pandemic Influenza.—Douglas Symmers, director of laboratories, Bellevue and allied hospitals, summarizes as follows the results of post-mortem investigations of influenza cases, and gives in detail the histories of two such cases in which death occurred without the intervention of pneumonic changes of other than negligible proportions. The cause of the so-called pandemic influenza has not yet been satisfactorily established. The initial effect of the provocative agent appears to be exercised on the vascular system, bringing about an extraordinary degree of capillary dilatation and injection, not only in the skin and in certain of the visible mucous membranes, but throughout the viscera, simultaneously, or approximately so. At the same time the blood pressure is low and the pulse may be slow, even in patients who have not received digitalis. All of these facts combine to show that the circulatory action of the provocative agent is more complex than that of any known single poison. The occurrence of intense injection of the suprarenal medullæ is common, however, and is sometimes associated with hemorrhagic extravasations into the substance of the gland, or even with thrombosis of the suprarenal veins. These changes in the suprarenal circulation offer at least a partial explanation for the low blood pressure as well as for the profound asthenia. In certain respects the anatomical changes in the vascular system in the so-called influenza are comparable to those encountered in the same situations as a result of the action of poisons, notably in some cases of death from acute methyl alcohol poisoning, and in certain instances of death from trinitrotoluene. The advent of the pneumonic lesions in association with the so-called influenza is secondary to injection of the bronchi and bronchioles, and of the intervesicular capillaries, these changes so lowering the resistance of the pulmonary tissues as to permit the entrance of infective microorganisms. The presence of exudative lesions in the cerebral meninges in the so-called influenza is likewise to be explained on the basis of circulatory disturbances followed by the invasion of infective microorganisms.

1. A New Germicide for Use in the Genito-Urinary Tract: "Mercurochrome-220."—Dr. Hugh H. Young and his associates state that during the past two years the research work in the laboratories of the James Buchanan Brady Urological Institute has been given over largely to the study of antiseptics, with a view particularly to the development of drugs applicable to the genito-urinary tract. Impressed with the possibilities of using dyes as a basis for the development of therapeutic compounds, efforts were concentrated on the production of new drugs possessing the penetrating qualities of dyes while at the same time being germicidal and relatively nontoxic and nonirritating. From among the considerable number of compounds produced in the pursuit of this research, mercurochrome-220 was selected for extended study. In synthesizing a drug for local use as a urinary antiseptic, it was sought to combine the following properties: (1) Ready penetration of the tissues in which the infection exists; (2) lack of irritation of the drug to tissues; (3) high germicidal activity; (4) ready solubility in water and stability of the solution; (5) freedom from precipitation in urine; (6) sufficiently low toxicity to avoid systemic effects from the small amount of the drug that may be absorbed. "Mercurochrome-220," the substance found to meet these requirements, is obtained by substituting one atom of mercury in the molecule of dibromfluorescin. Chemically it is dibrom-oxymercury fluorescin, or its sodium salt. The latter contains 26 per cent. of mercury. The observations and experiments carried out in order to determine the conformity of "mercurochome-220" to the requirements named are given in detail, and ten cases in which the substance was used are reported.

From the experimental and clinical evidence obtained by them, the authors draw the following conclusions: (1) Mercurochrome-220 is experimentally a drug of great germicidal value, a solution of about 1:1,000 killing *B. coli* and *Staphylococcus aureus* in urine in one minute. It has practically fifty times the germicidal strength of acriflavine in urine medium for exposures of one hour. (2) In a strength of 1 per cent. the new drug is tolerated by the human bladder for from one to three hours without irritation. Injections of 1 per cent. solution into the renal pelvis are likewise free from pain, even when held in situ by plugging the catheter. (3) That mercurochrome-220 has a remarkable germicidal value is shown by the rapid sterilization accomplished in a series of cases of cystitis and pyelitis of long standing and refractory to other treatments. Now for the first time we feel that we have a method of quickly curing certain chronic infections of the bladder. The rapidity with which a few cases of old purulent cystitis disappeared was surprising, becoming free of pus and bacteria in a few days. (4) Studies of the comparative value of acriflavine and mercurochrome-220 in gonorrhea are not yet complete, but it has been demonstrated that with both drugs, methods of great value in the treatment of the disease have been produced. (5) Mercurochrome-220 has proved to be eminently satisfactory in the treatment of chancroids, and as a dressing for buboes after incision.

6. Some Remarks on "Spanish Influenza": Its Nature and Etiology.—Alexander Edington took charge of Grey's Hospital, Pietermaritzburg, Cape Colony, in January, 1918, and admitted cases of influenza every month from that time onward. In the majority of cases the malady was uncomplicated, but in some there followed a true influenzal pneumonia of the type so common in the Edinburgh epidemic of 1889. Only one case died up to October, 1918, but about the 12th of that month there was an enormous rush of cases, and between that date and the end of the month 234 cases were admitted, of which 41 died (29 natives and 12 whites). In the 1889 epidemic there was no heavy mortality, although following in its wake there was a large mortality from other diseases, especially tuberculosis. In the case of the so-called "Spanish influenza," however, the mortality was so enormous as to raise a grave doubt as to whether this mortality was actually attributable to influenza or to some other more malignant infection. From his study of the symptoms, the post-mortem findings, and the bacteriological investigation, Edington satisfied himself that the malady is a definite infective disease of high virulence. Examination of the scanty sputa of the delirious cases showed, in some cases, the presence of bacilli of the plague type, but not absolutely typical. One could not say that the bacillus isolated was actually the cause of the disease, although the fact of finding it so often, and the results obtained by inoculation were certainly very suggestive. It was one of the most pleomorphic organisms with which he had ever dealt, following very much the line of bubonic plague bacilli. When grown in bouillon for six hours, examination after staining with carbol-methylene blue showed bacilli with rounded ends clearly giving a bipolar staining. On agar the growth was that of bacilli mostly, and after a few days' growth there was great evidence of denegeration of the bacilli. One found many of them with ends looking as if irregularly broken off. He had never seen such a peculiar condition before in any bacillus studied. The growth on agar was at first fairly profuse, but if removed from the incubator and allowed to grow at ordinary room temperature one found a secondary growth taking place. Edington was at a loss to account for the manner of the spread of the disease. He had not seen a case arising from direct infection. Although a heavy percentage of the nurses in the hospital went down it was from simple uncomplicated influenza from which all recovered. The cases could be diagnosed very soon after admission, in some cases, especially if there were no lung symptoms, if the temperature was not over 104°, and if the nervous condition was well marked. Cases in which a moderately high temperature remained high for 48 hours without lung symptoms were to be regarded with suspicion.

Another type of cases seen was that in which the patient was admitted with a rising temperature which formed a curve extending over about five days, dropped to nearly or quite normal, and was then followed by a sharp rise and remained high. As regards treatment, in Edington's experience nothing seemed of great avail. He attempted to treat the delirium as soon as possible, finding ammonium bromide particularly beneficial. Where this proved insufficient, under a dosage of 10 grains per hour, paraldehyde, chloralamine, or hyoscine might be used. He considered morphia as contraindicated, as tending rapidly to permit pulmonary edema, which is the forerunner of a fatal issue. The disease would seem to be one affecting the cerebrospinal nervous system, and to be more irritative than inflammatory. Pulmonary and other conditions which might supervene might be regarded only as complications, arising from the disorganization of the nervous system.

3. The Scope of Certain Gaseous Disinfectants in the Prophylaxis of Influenza.—Alexander Gregor states that since the publication of his note on the epidemiology of influenza among gas workers (*British Medical Journal*, March 1, 1919), evidence has been accumulating that people working in an atmosphere containing certain gases obtain a marked degree of immunity during outbreaks o finfluenza. In the present communication he describes experiments undertaken with a view to determining the value of SO_2 and NO_2 respectively for the present purpose. He summarizes the problem for investigation in two questions: 1. Is there any epidemiological evidence to show that workers in fumes are less attacked by influenza than others? 2. Is there any evidence to show that the fumes emanating from these manufactures have any influence on the vitality of bacteria in the post-nasal secretion of persons inhaling them? From available statistics the first proposition is answered in the affirmative. Concerning the second, it is held that it goes without saying that if a practical measure for preventing the spread of influenza by means of a disinfectant gas is to be elaborated, the concentration of this gas must be such that while exerting the requisite action on the secretion of the upper respiratory passages of those inhaling it, no untoward effect is produced. In this connection it is stated that throughout the experiments with SO_2 and NO_2 gases the concentration of these gases in the air of the room was so small as to be comfortable outside the limits of their toxic action. *A priori* it is exceedingly improbable that sterilization of the secretions of the upper respiratory passages can be effected by even prolonged inhalation of disinfectant gases in such low concentration as now under consideration. The problem, however, is not one of sterilization, but of checking the spread of influenza; and it is conceivable, and even probable, that a moderate degree of disinfectant action on the secretion of the upper respiratory passages, while falling considerably short of complete sterilization, may nevertheless be of very great value in limiting the spread of infection, particularly if the action is such as to render this secretion even moderately unfavorable to the multiplication of the invading microorganism. The methods used in Gregor's experiments were suggested by Gordon and Flack in their observations on the disinfection of meningococcus carriers by the use of steam spray. The use of the spray with high pressure steam did much toward the reduction of mass infection in meningococcal infection among troops, and the attempt is now made to show that even better results can be obtained by using gases. The difficulties of applying the spray to masses of the civil population in times of epidemic are almost insurmountable, whereas in the form of gas a certain degree of disinfection of the upper respiratory passages could be brought to practically every home. The experiments are given in detail, and the practical application of the findings to men *en masse* are described. From these observations the following summary is formulated: 1. Workers in gas fumes have shown a certain amount of immunity during recent waves of influenza, as compared not only with other classes of the community, but also, in one instance, with those working in the same factory, but not in a fume department. 2. Post-nasal swabs taken from employees at the time of working, and also after being twenty-four hours off duty, showed either a very marked decrease in the growth of microbes in nearly every instance or were sterile. The same observation holds good in regard to non-workers experimented on in the works and in the laboratory. 3. With one exception—namely, SO_2—plates inoculated with the *Staphylococcus epidermidis*, and exposed to the fumes of the factories, showed a marked diminution in growth, and in one instance sterility was attained. 4. SO_2 had no action on inoculated plates. But when this and other selected gases were bubbled through suspensions of organisms, in various liquid media, the growth was completely inhibited. 5. It has been definitely proved that groups of men can be exposed to NO_2 and SO_2 gases for lengthened periods during epidemic times without the slightest discomfort or harm to anyone. 6. There was no evidence of nasal irritation and consequent increased flow of mucus among the workers. Further, it was noted that among non-workers exposed in the works, in the laboratory, and in the inhalatoria, any initial irritation caused by the fumes quickly disappeared, and that tolerance was quickly established. 7. The nasal secretions after exposure were always found to be acid. 8. It is suggested that the mode of action of NO_2 and SO_2 fumes may be that as the secretions of the upper respiratory passages are rendered acid a medium is formed which is inimicable to microbial growth.

Gazette des Hôpitaux.

September 27, 1919.

Meningeal Reaction and Albuminuric Retinitis in the Course of a Mild Azotemia.—Professor Roger describes the following case: A German governess, aged 27, was attacked with headache, vomiting, and denutrition. The urine was negative. The viscera were all intact, and a diagnosis of psychoneurosis was made temporarily. The patient entered the Salpêtrière Hospital, and was placed on a milk diet. This conjoined with isolation produced improvement. However, the case underwent an exacerbation in that the old symptoms came on intermittently. The vision now showed beginning impairment and the oculist found albuminuric retinitis. The patient was therefore transferred to another hospital. The original symptoms were now aggravated, and nosebleed was added. The kidneys were normal on palpation; albuminuria 1:1000. Lumbar puncture relieved the headache, and the punctate showed absence of leucocyte reaction. The patient was also bled and the blood was examined quantitatively. The process was rapidly becoming worse, and to the picture were added convulsions and delirium with cyanosis. A second venesection gave relief. The spinal fluid now gave a leucocyte reaction, and showed a yellow tint. The patient recovered sufficiently to go to Germany, where it was learned that she had succumbed after an operation presumably decortication of the kidney. This episode was before the great war. The most notable feature of the case was the marked meningeal reaction. Not many cases with spinal fluid finds are on record. Among the finds in the present case was hyperalbuminosis, characterized as intense, with moderate hypercytosis—8 leucocytes to the cu. mm. This represents a dissociation—marked hyperalbuminosis plus slight hypercytosis. This phenomenon has thus far hardly been seen in uremia. To this should be added xanthochromia, already mentioned. Meningeal reactions with spinal fluid finds are seen in various conditions, especially apoplexy. A few red corpuscles in the spinal fluid showed the probable occurrence of a slight cerebral hemorrhage. The blood urea was such as to show the presence of very slight azotemia, whereas in other similar cases the nitrogen retention has been very great. Hence the degree of meningeal implication does not stand in any definite relation to the degree of azotemia. Hence a mild azotemia can cause a fatal result through some mechanism not clear but perhaps latent cerebral hemorrhage.

The Coolidge Tube in France.—A monograph on this subject has been published by Pilon, a review of which in the *Brazil-Medico* for June 7 calls attention to the intensive study of surgery during the war years. The labor of five years of war corresponds to at least 20 years of peace and this applies equally to the *x*-rays. At the outbreak of the war the Coolidge tube was not much in use and the question at once arose should the *x*-ray equipment of the war be domestic or foreign. The latter view prevailed and the Coolidge tube became the official one for France. Practically every radiographer uses this marvelous instrument.

Book Reviews.

Today's World Problem in Disease Prevention. By John H. Stokes, A.B., M.D., Chief of the Section of Dermatology and Syphilology, the Mayo Clinic, Rochester, Minn.; Assistant Professor of Medicine, Mayo Foundation Graduate School, University of Minnesota. Issued by United States Public Health Service, Treasury Department, Washington, D. C.

The work consists of four parts, the first a sort of general introduction which comprises an account of chancroid, while the second and third are devoted respectively to gonorrhea and syphilis and the fourth to the social, psychologic and economic background of syphilis and gonorrhea. We find a vast deal of compiled information relieved of its dryness by attempts to visualize the horrors of the venereal plagues. We regret that the author, like many of his cowriters on these subjects, adheres to the American origin of the disease, having apparently followed a well-known literary adventurer to the exclusion of recent *bona fide* historical labors.

John Coakley Lettsom and the Foundation of the Medical Society. Being the Presidential Address Delivered Before the Medical Society of London on Oct. 8, 1917. By St. Clair Thomson, M.D., F.R.C.P. Lond., F.R.C.S. Engl. London: Harrison and Sons, 1918.

This brochure contains 62 pages with 4 plates and 14 figures and in England sells for 2 shillings and sixpence. To quote the publisher's notice, Lettsom in his daily activities between 1773-1815 used 3 teams of horses, earned from £5,000 to £10,000, wrote essays, lectured and mingled in the best social circles. His enormous acquaintance with prominent people extended to the United States and he was honored by membership in fifteen American societies of various kinds, as historical, agricultural, medical, antislavery, humane, etc. He was an LL.D. of Harvard, an honorary conservator of the New York Hospital, Fellow of the American Academy of Arts and Sciences, etc., etc. In 1773 he founded the first of the London medical societies. For some unknown reason a list of his numerous publications is omitted.

A Textbook of Materia Medica for Nurses. By A. L. Muirhead, M.D., Professor of Pharmacology, Creighton Medical College, Omaha, Neb. St. Louis: C. V. Mosby Company, 1919.

The 24 short chapters of this small volume are devoted chiefly to drug classifications, as disinfectants, purgatives, anodynes, hypnotics; and to individual drugs and drug groups, as alcohol, the strychnine-caffeine, atropine-pilocarpine, and numerous other groups. The chapter on alcohol suggests that the author is not too optimistic concerning a bone-dry country, for some space is devoted to the effects of its abuse; while beer and wine receive mention as stomachics. Under anodynes, heroine is mentioned as an antitussic, while codeine is useful with but small risk of abuse. The views of textbooks issued in the coming years on alcohol and narcotics will be of much significance, for with a dry country authors can speak with greater sincerity than heretofore of recent years.

Venereal Diseases. A Practical Handbook for Students. By C. H. Browning, M.D., D.P.H., Director of the Bland-Sutton Institute of Pathology of the Middlesex Hospital; and David Watson, M.B., C.M., Lecturer on Venereal Diseases, Glasgow University; Surgeon in Charge of the Venereal Department, Glasgow Royal Infirmary and of the Lock Hospital, Glasgow. With an Introduction by Sir John Bland-Sutton, F.R.C.S. London: Henry Frowde, and Hodder and Stoughton, 1919.

The first part of this book deals with syphilis, and the last part deals with gonorrhea. Chancroid is discussed in a few lines inserted as an addendum to one of the chapters in the part on syphilis. The authors have produced an eminently satisfactory book, giving in a concise form just what the student and practitioner require on this important branch of medical practice. Early diagnosis and adequate treatment are especially emphasized; and the laboratory procedures are discussed with the degree of detail necessary to make them available for daily use. The size of the book is attractive; so, too, are the printing and the illustrations. The study and practice of the teachings contained in this volume should do much toward the prevention as well as the cure of venereal diseases.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia; assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. September 1, 1919. Philadelphia and New York: Lea and Febiger.

The current number of Progressive Medicine is only about half the size of its immediate predecessors. It contains chapters on diseases of the thorax and its viscera, including the heart, lungs, and bloodvessels, by W. Ewart; Dermatology and Syphilis, by W. S. Gottheil; Obstetrics, by E. P. Davis, and Diseases of the Nervous System, by W. G. Spiller. As usual, the publication is both interesting and valuable.

Experimental Pharmacology. By Hugh McGuigan, Ph.D., M.D., Professor of Pharmacology in the University of Illinois, College of Medicine, Chicago, Ill. Illustrated with 56 engravings and 7 colored plates. Philadelphia and New York: Lea and Febiger, 1919.

Medical students, with their passion for outlines, with their love for the one-two-three-four method of presentation, will probably give Professor McGuigan's book a hearty welcome. It is the kind of manual which will be hallowed by spots from reagents as it lies open on the laboratory desk. The experiments have been excellently selected, and comprehensibly described. As for the author's use of the outline method in describing the action of the different drugs, there can be no objection to this, if the book be used as the author clearly intended that it should be used, namely, as a manual for ready laboratory use to head the student toward more complete works on the objects of his experiments. Only the mediocre student will make this outline his pharmacologic be-all and end-all. In its proper and intended place, then, the book is a valuable addition to the list of pharmacologic text-books.

Symptoms of Visceral Disease. A Study of the Vegetative Nervous System in Its Relationship to Clinical Medicine. By Francis Marion Pottenger, A.M., M.D., LL.D., F.A.C.P., Medical Director, Pottenger Sanatorium for Diseases of the Lungs and Throat, Monrovia, Cal.; Professor of Diseases of the Chest, College of Physicians and Surgeons, Medical Department, University of Southern California, Los Angeles, Cal. With eighty-six illustrations and nine color plates. St. Louis: C. V. Mosby Co., 1919.

One of the most interesting features of Dr. Pottenger's new book is that the author, so long a specialist in pulmonary disease, should have ventured into a field already ably covered by Head, McKenzie, and others. In this book we see the specialist realizing that he cannot escape a principle which involves all the specialties. So he turns aside for a thorough consideration of the principle.

Emphasizing the paramount importance of the patient and his symptoms and signs, Dr. Pottenger devotes the major portion of his book to the viscerogenic reflex as an explanation of many of the patient's complaints and the physician's findings. The subtle, frequently overlooked manifestations of these reflexes lead the author to stress careful clinical observation as a means to obtaining fullest returns from the principle set forth.

The book presents a much more elaborate discussion of the parasympathetic reflexes than is to be found in other writings. The treatment of this subject leaves one thoroughly impressed by the manifold duties and powers of the vagus nerve. Almost entirely new is the author's treatment of the interference with tissue nutrition by the reflex effect of visceral disease—a phenomenon considered as the "viscerotrophic reflex."

The reader of the book, be he specialist or general practitioner, is given an interesting point of view from which to study the manifestations of visceral disease.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 2, 1919.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

The Wesley M. Carpenter Lecture.—The Increasing Socialization of Medicine.—Sir ARTHUR NEWSHOLME, late Principal Medical Officer of the Local Government Board of England; Lecturer on Public Health, Johns Hopkins School of Hygiene, delivered this lecture. He said, in part, that medicine had always been the most altruistic of professions and could proudly claim that its practitioners had ever been ready to give gratuitous assistance to all in need of it. Each medical practitioner in his own circle, and to the extent of his medical competence, was a medical officer of health, having more influence in directing and controlling the habits and occupations, housing and social customs, the dietary and general mode of life of the families to which he had access, than any other person. He had even more influence than the minister of religion in regulating the ethical culture of his patients, especially as regards alcoholism and the sexual vices. Incidentally he expressed the opinion that the restriction of the consumption of alcoholic beverages would reduce the income of practising physicians throughout the American Continent and at the same time diminish crime, accidents and sickness. The term "Socialization of Medicine," he explained, included the rendering available to every member of the community, irrespective of any necessary relation to the ordinary condition of individual payment, of all the potentialities of preventive and curative medicine. Preventive medicine was gradually lengthening the span of human life with the prospect of rapid reduction of tuberculosis, syphilis, and gonorrhea. Between 1871-1880 and 1910-1912, in England, there had been an increase of ten or eleven years in the average duration of life. To appreciate this one need only review the early ages at which many well-known persons died a generation or two ago. Preventive medicine had almost completely annihilated typhus fever in this country and in Great Britain, it had reduced the incidence of enteric fever, and almost abolished smallpox. There was also a list of medical triumphs in tropical diseases, and all were familiar with the achievements of modern surgery, made possible by the discovery of anesthesia. He said he was not unmindful that respiratory infections, cerebrospinal fever, and poliomyelitis were diseases in which the flag of public health had not yet been firmly placed. Tuberculosis would become a controllable disease as soon as physicians, public health authorities, and the patients themselves would combine to adopt measures already within reach. Health was always less costly than disease and this was especially true for tuberculosis.

The ever increasing importance of hospitals was discussed and their evolution from voluntary to State institutions traced. Statistics quoted showed the extent to which institutional treatment was replacing domiciliary. As one instance of this might be cited the statistics with reference to the deaths from tuberculosis, which showed that in England and Wales 34 per cent. of male deaths and 22 of female deaths occurred in hospitals: in London 59 per cent. of the male deaths from tuberculosis occurred in hospitals and 48 per cent. of female deaths. This was not only important as indicating better care for the sufferer but also from the standpoint of the prevention of the spread of the infection. General and special hospitals could be shown to be important agents, not only in reducing the fatality of disease and in effecting a more rapid restoration to health of those affected, but also in reducing the incidence of such affections as tuberculosis, syphilis, and other diseases. Hospitals have proven to be a great factor in overcoming the handicaps of urban life. In spite of the deleterious influences of overcrowding, statistics showed that the death rate of urban populations was less than that of rural districts. The reasons for this were that parturition was freer from risk in towns than in remote country districts; the means for the provention of infection were better organized; accidents and diseases were more promptly and efficiently treated; the poor received better treatment gratuitously than in rural districts, and the hospital served to relieve housing inefficiency in the town in times of sickness.

The medical record of the past was that of increasing control over infectious diseases. In securing this result epidemiologists, pathologists, and vital statisticians, aided by the sanitary and industrial inspector, had been instrumental. However, we could not be satisfied with the degree of success obtained. At least one-half the mortality and disability still occurring at ages below 70 years could be obviated by the application of medical knowledge already in our possession. The high percentage of defects in English and American recruits brought out by the draft examinations, as well as similar revelations brought out by the physical examination of school children, served to emphasize the need for the application of preventive medicine on a larger scale than at present, and all along the line, commencing with prenatal care and continuing through the preschool age, the school age, and during adult life. The present extent to which the socialization of medicine had advanced was shown in the voluntary hospitals and institutions, the Poor Law infirmaries, fever and tuberculosis hospitals, lunatic asylums, etc. The speaker outlined the functions of the Poor Law and of Public Health organization and quoted statistics showing the large number of physicians engaged in this work, showing the extent to which the State, apart from national insurance, was giving a rapidly increasing amount of medical assistance to the public. Under the Poor Laws, destitution, lunacy, and feeblemindedness were provided for. Public health authorities to a limited extent provided domiciliary treatment of infectious diseases. Tuberculosis sanatoria were provided by the Public Health authorities before the introduction of health insurance legislation. Maternity and child welfare work was carried on by local authorities and one-half of the approved expenditure incurred by local authorities was met by the Central Government. For the control of venereal diseases the Central Government went still further and contributed three-fourths of the total cost of maintaining clinics for the treatment of these diseases. The law went even further and prohibited the treatment of venereal diseases by unqualified persons and also the advertisement or sale of remedies for these diseases. The Public Health authorities were giving gratuitous laboratory tests to private physicians. Medical inspection was made of each scholar in the elementary schools several times during the nine years of his compulsory attendance at school and treatment for physical defects was provided when necessary. In addition to these services there was the work now being done by the Pension Department. In spite of all these activities, that the work done on behalf of the community *plus* the work accomplished by private practitioners was not equal to the national needs was obvious to any one considering the vast amount of avoidable disease. The medical provision made in a large proportion of cases was belated and inadequate and commonly did not include the full resources of medicine.

The speaker showed that it was regrettable that Poor Law medicine and Public Health medicine were not combined when the English Government Board was formed in 1870, and stated that the separation of the two problems of poverty and sickness was inconsistent with a full measure of success in handling them. He then discussed somewhat at length the National Insurance Act of 1911 which gave sickness and invalid benefits to all employed manual workers and others whose income was below 160 pounds per annum. This insurance act had further complicated the administration of already existing medical services of the Poor Law, Public Health, and educational authorities and had converted the majority of general practitioners into part time civil servants. Bismarck's attempt to counteract specialism with insurance had been responsible for State and official experimentation in insurance which, at least in England, was not actuarily, financially, or medically well advised, and which had involved expenditure in administration entirely incommensurate with the benefits received. It diverted into

an unsatisfactory channel the energy and money which were urgently needed for the immense good obtainable by reforming Poor Law and Public Health administration. With the principle of contributory increase to cover monetary support during illness there could be no quarrel, but in the interest of national efficiency, complete medical provision, preventive and curative, must be made by the State irrespective of insurance, and the medical practitioners employed in the certification of such insurance work must be employed under conditions which rendered them independent of the insured and would enable them to utilize their knowledge of each patient's case for such preventive measures as were needed, whether these were concerned with the sanitation of the home, factory, workplace, or with personal habits.

In considering the needs of the future the speaker forecast that the State would from year to year take an increasing hand in medical matters. It was useless to attempt to oppose the inevitable and eminently desirable trend toward the increased utilization by the State of preventive medicine. It was for physicians to guide the course of events. He then outlined a plan by which all forms of public medical service should be linked up with the public health service. Each subdivided unit of public health service which should link curative and preventive medicine would have a hospital center about which should cluster dispensary service, all special services, a domiciliary nursing service, maternity service, and infant welfare work. He also urged the reconstruction of the training of medical students to the end that they might receive proper training in preventive medicine in its broadest sense. The teaching of medicine would be more physiological and hygienic than at present. All this would cost money, but sound health was a national asset and disease was always more expensive than health.

Dr. George David Stewart, on behalf of the members of the Academy, extended thanks to the speaker of the evening for his interesting and scholarly address.

Anniversary Meeting, Held November 6, 1919.

The President, Dr. George David Stewart, in the Chair.

The Anniversary Discourse—New Men for a New Era. Rev. Charles Aubrey Eaton delivered this address. He said, in part, that he did not expect to pay much attention to his subject though he might get within speaking distance of it during the evening and if he did he would hail it. He had come to them out of the heat and stress and storm of peace days to share with them certain conceptions. He was not sure, he declared, just what was going on, but he felt that it was the duty of every man to interpret in so far as he could the present tangled social condition. As a lad he had formed a philosophy of history which he had never had occasion to change; this was based on the idea of the progressive spirituality of life. He believed man was his soul and nothing else was man, the nation was its soul and nothing else was the nation. He found in history times when a nation prospered in arts or science, and he could always trace it to a fundamental spiritual awakening. He was not interested in the outside of men. He had lived up and down the social scale all his life. He had lived with the very wealthy and the very poorest and all in between, and to save his soul he could not find much distinction between them. He had attended the funeral of a wealthy man on Fifth Avenue amidst all the pomp and ceremony that money could buy just after coming from the funeral of a poor little girl on the East Side, and the one fact that impressed him was that the rich man was just as dead as the poor little girl, no more so and no less so. In the last analysis of our human nature the quality and essence of our being was the same. The Bible told the truth when it said God made of one blood all the nations of the earth. In the normal, sane man one found the consciousness that this world was a good place, and that underneath and behind and around was an infinite purpose upon which he could rest his poor ignorance and which could eventually bring him through all his struggles to the portals of peace.

In attempting the analysis of conditions that surrounded us at the present time we first waked up with a start to find that in spite of our material advantages we were no happier than our fathers. The men before him this evening lived in palaces and had all the evidences of wealth and culture and farmers like himself wondered how it must be to live that way, but when they got together and talked it over they found there was not much difference between them after all. The real inner man was just the same human being that he was when they were lads, and all this fuss and feathers about externals was absurd lunacy. He was not impressed by the magnitude of our material resources. He was not sure that a man was rich if he did not have time to lie on his back in the cool green grass and look at the sky and hear the throbbing of God's purpose in Nature about him. That man was richest who, having enough to satisfy his needs, was equipped to use his physical, intellectual, and spiritual forces in service. That man was rich who was a part of a wholesome family life where the members of the family were mutually dependent on one another; when individuals in a family ceased to need each other there was nothing left. Family life with its service for others and its simple life was richest in the awe and mystery and wonder of its dreams and ideals; no one was rich without these, and no one was poor who had them. That was out of touch with the popular form of insanity for the moment. He was confident that the majority of people at the present moment were crazy. All of them were crazy a part of the time, and the majority of them were crazy all the time. The world was becoming a glorified lunatic asylum. As an instance, he described the popular form of music, the jazz band, and the popular dance, which was nothing more or less than the "snake dance" of the savage; stripped of its flummery it was a form of insanity and degeneracy, a reversion to the jungle of Africa.

Civilization, in its forward progress, seemed to take one instrument at a time. At times war was the chief instrument. Again, as in the great age of the Hebrews, and in the Middle Ages, religion was the chief instrument of progress. At other times art was the motive force of progress in civilization. To-day the chief organ of civilization was industry, not the industry expressed in the handiwork of the individual, but industry on a colossal scale, until men worked as impersonal machines. That was the outstanding interpretation of the age in which we lived; emphasis was laid on the machinery, on the externals. In the mid-Victorian era Charles Darwin published the "Origin of Species." For generations man had been looking for a great organizing principle to explain the manifold expressions of all things in the physical universe, and Darwin had interpreted and correlated physical phenomena under a new principle. This principle was the law of the survival of the fittest, and natural selection. That was the principle supposed to apply in the natural sciences, and it was supposed that out of it would grow a great mastery over the forces of Nature. But every great principle had the possibility of being applied in realms outside of those for which it was intended, and this principle almost immediately overflowed the realms for which it was intended. It first overflowed into the realms of theology, and then entered business, and now it had entered history. Here the attempt was made to give a new interpretation to history. The principle had gravitated to a rich soil congenial to it. Only one nation attempted to interpret its affairs with this as the organizing principle, and that was Germany. In two generations Germany, the inheritor of the ideals of Luther, Germany which had lifted the torch in the blackness of the Middle Ages, became the incarnation of brute force, and of the principle of the right of might. Through science the mastery over physical force was obtained, and it followed logically that Germany leaped out on the world stage to demonstrate the power of this principle. Her first postulate required the overthrow and destruction of other systems in order that she might create what was expressed in the phrase "Deutschland über Alles."

For five years the minds of men had been devoted to the science of destruction. We had seen the work of centuries destroyed in a moment by a cannon ball.

For five years the chief business of man had been the killing of men and the destruction of property. The abnormality of this life we had hardly apprehended. That human beings could have endured what they had during this period was past belief. Even as late as last August black horror hung over the scenes of battle; the air was still foul with the stench of decaying human bodies; 12,000,000 French people were without roofs; vast areas were without a house, or a hope, or a smile. All that had laid hold on the world, and in addition to the new facilities for destruction we had acquired new facilities for spending. The European nations had been spending borrowed money for five years, and not spending it in ways constructive and permanent. It had been put into cannon ball, gunshot, and powder, and in addition to this waste there was the waste of what it cost to produce the men that were killed, and beyond this again was the waste in the men who did the killing. In the stress and strain of war their nerves had been shattered and their mental outlook on life altered. It would take years before they gained control of their nerves and adjusted themselves to life. In Germany Karl Marx had evolved theories that had spread all over the world, and according to these theories competing methods must be destroyed. In view of these things it was small wonder that emphasis was placed on destruction, especially when one took into consideration the fact that this was a mechanical age that had lost the influence of spirituality. It was small wonder under these conditions that feeble minds and those to whom war had brought heavy grievances should be devoted to the idea of destruction. Nor was it strange that this idea had grown until it was decided that capital for profit and labor for wages must go. It was not surprising that with this background we should have the conflict between capital and labor.

What was to be their preparation to meet these conditions? Dr. Eaton said he would not suggest anything for Europe. Europe would have to fight for its own life, on its own soil, and in its own way. We had in our own country one hundred and ten million people; we were unfortunately the richest nation in the world; we were the only nation that got rich in the war. We had arrived on the scene too late to have suffered any mortal wound. We had not suffered as they had suffered in England, or France, or Belgium, yet when he returned home from these countries he found our nation even more unsettled and disturbed than France or Belgium, and the unrest continued to increase. His task was that of an industrial expert; he went as the interpreter of the spirit. The thing that had gone out of life was personal relationship. The employer should be the leader of his men. We did not need the professional deliverer; the employer should fulfil this function. The people should look upon the employer much as a son upon his father, a student upon his teacher, a citizen upon his political leader. But employers were organized into corporations and corporations had no soul, and employees were organized into unions also apparently without a soul. The result was an ill will that cut down production 40 to 50 per cent. He had seen production lifted from 30 to 100 per cent. within a few weeks under the influence of personal contact with the right kind of leadership.

Facing life as we did to-day, with its unrest and its challenge, the question confronting us was, "What are you to do and what am I to do?" We must fix in our minds certain things that are not going to be destroyed. He had been in England during the railroad strikes, and the people of England had shown an even finer spirit than in the war. There the Government said that if its employees struck they could not come back to their positions. He believed in the right to strike, but not for public servants; they could resign, but they should not desert their posts any more than could the soldier in the face of the enemy. When he returned home he found the Boston police in a strike, but fortunately there was an American in the State House, Calvin Coolidge, who stood out against all newcomers and protected the fundamental principles of the American Government. The Boston police strike awakened in the minds of the people the necessity of preserving the fundamental principles of the American Government unchanged. The superstructure could be changed and often had faults that needed changing, but the foundations must remain sacred and untouched by the hand of any rebel. In questions of policy one might be a partisan, but where the fundamental issues were concerned one must be first and always an American. It ill became him, he declared, to tell learned people like those before him what they should do, so he would only tell them what he was trying to do. The thing we had to have in America was a spiritual awakening. We were spiritually dead. He knew nothing about medicine, so he begged their indulgence for speaking on a medical subject, but he had noticed that nervous prostration was the prize possession of people with little mental ability and not much character, accompanied by a great deal of molecular activity. He had known instances where a robust peasant woman who did the family wash and all the other housework, when she became prosperous moved from her three-room cottage, and had nothing to do, developed nervous prostration in a few years. A great many fine ladies about this town would be better off if they would discharge some of their help and acquaint their hands with the sacrament of dishwater, and even cook, if their husbands could stand it. There were nerves intended for three kinds of activity, the physical, intellectual, and spiritual. All must function and in the proper proportion. The more a man did the fewer nerves he had. The surgeon doing the most exacting work, even into advancing years, did not complain of nerves. It was the people who did nothing who suffered from nervous prostration, and for these he suggested work. Solemnly, as a lover of his kind and a student of human nature, he believed there was no hope for us without renewed spirituality. We would not see the age of kindliness, peace and repose, of efficiency and brotherhood between man and man, until we found a spiritual basis on which it could be established, and this did not mean a revival of religion in the churches. His own idea was that the church was as badly off as the rest of us; it was a spiritual vacuum. Religion had become a technical thing, an affair of mystery, ceremony, and ritualism administered by a priest. Many seemed to believe that the church was the only place where God was, and to any one who realized the central place which religion held that was a tragic situation. We needed a spiritual awakening, but that did not mean new denominations or new creeds, but the awakening of a certain class of experiences, those elemental, eternal relationships which we had gotten so far away from. In our struggle for material civilization, God had disappeared out of our sky. But the hunger of the heart for the peace of God that passeth all understanding lay deep in the human soul and would come back in the silence and mystery and glory of that simple life which was the only life. Dr. Eaton declared that he said these things not as a preacher, because he had left the pastorate to go into the ministry. He was not waiting for people to come to him to be saved; he was going out where men were because where men were there God was, and he wanted his hearers to do the same. He wanted the newspapers to become ministers of God's message; he wanted business men to become the prophets of God; he wanted the laboring man to come with the spirit of brotherhood that would be met half way by the big manager of labor; he wanted the professor to leave dry bones and get a glimpse of the soul. If we were not all prophets of God, from the wealthiest banker to the humblest laborer, then there was no Kingdom of God. God was as much in Sing Sing Prison as in St. Patrick's Cathedral, or the Cathedral of St. John the Divine, or the Baptist Church. The Kingdom of God was where men were, or it was not anywhere at all. It took a man-sized man to put that into practice. While we had struggled for scientific achievement and for material prosperity we had forgotten that a big tree that would weather all gales must have big roots, and no man grew unless he had his roots deep in the nature of God. There could never be unity among men by any artificial means. Men could never be united

except by finding unity in the Lover of Souls. He was preaching the gospel in workshops and factories, and if he were asked to be depressed and anxious he could not be, because he knew it was God's world, and some day we would invite Him to come back into the world from which we had exiled Him and would enthrone Him in our minds and hearts.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 28, 1919.

THE PRESIDENT, DR. CHARLES H. PECK, IN THE CHAIR

The Schick Test and the Immunization of Children against Diphtheria: A Communication.—Dr. WILLIAM H. PARK stated that he had asked that he might be permitted to make an announcement in order to let the physicians of the community know what the Department of Education and the Department of Health were doing in the direction of applying the Schick test and immunizing school children against diphtheria, so that when they were asked they would understand and would advise their patients to have the test made and to be immunized if that was necessary. Perhaps it was known that there had been one-third more diphtheria cases this winter than last. When Dr. Copeland noticed this increase in the number of diphtheria cases he asked Drs. Harris, Baker and the speaker to make suggestions as to the course to be pursued. He had advised the use of immunizing injections of antitoxins for the children in invaded families, and early and large doses of antitoxin for the cases of diphtheria already developed, but he especially advised the general use of the Schick test and the active immunization of all infants and children found susceptible to diphtheria. It was now known that three injections of the toxin-antitoxin would give immunity in 95 per cent. of the cases and that this immunity would develop between the fourth and twelfth week and would persist for at least 3¼ years. It was hoped by the production of artificial immunity by the administration of the toxin-antitoxin to hasten the development of the natural immunity that took place in a large number of individuals between the age of one and twenty years. Dr. Ettinger and Dr. Copeland had agreed to start with the primary and kindergarten schools to make the effort to offer this protection against diphtheria. The children would receive a statement to take home, saying that the Department of Education and the Board of Health approved of the Shick test as a means of ascertaining whether or not a child was susceptible to diphtheria, and in case a child was not immune, immunity could be conferred which would probably last throughout life by the administration of a few injections. If the parents approved of this the children would be given the Schick test and, if this showed it to be necessary, two immunizing injections. At the next term they would again be tested and the few who were still susceptible would be given a second series of two injections. In a trial test where the parents were first appealed to and then instructed through the circulars, about 80 per cent. of the children were reached. The work would be begun about May 10 in a few schools in each borough, and if the plan met with success it would be extended in the fall. It was important that physicians should understand the plan and the results, namely, that from two injections immunity could be expected in 90 to 95 per cent. of the cases, which would persist at least three years. The injections were absolutely harmless. They had injected 1,950 babies from three to five days old without the slightest sign of harm. The older the child was the greater the protein reaction. The reaction was more severe in adults than in children. This was due to the presence of peptones and other foreign proteins in the broth and not to the toxin-antitoxin itself. Since about nine-tenths of all deaths occurred in children under ten years of age, it did not seem worth while to immunize the adult population, with the exception of nurses. The method of administering the toxin-antitoxin was to inject 1 c.c. subcutaneously or intramuscularly with the finest needle. Among 4000 injections given to small children, they had not had one serious or annoying reaction. Dr. Park said he hoped that when parents asked the physician whether it was advisable to be immunized against diphtheria he would advise them to have their children submit to the Schick test and receive the immunizing doses of toxin-antitoxin if necessary. He was looking forward to a not distant time when the entire infant population would be immunized against diphtheria.

The Irritable Heart in General Practice: A Comparison Between It and the Irritable Heart of Soldiers.—Dr. SELIAN NEUHOF presented this communication which he summarized by stating that the irritable heart as observed in general practice was similar to that found in soldiers. Vasomotor symptoms were more pronounced in the former. The etiological factors were similar, but because of training and war conditions, dormant and latent neuroses cropped out oftener, and were more readily evoked; consequently the cardiac syndrome was more violent and lasted longer. Infection was a factor only in so far as it induced and produced nerve and muscle fatigue, and psychasthenia. There was no pathological change in the cardiovascular system. The fundamental cause of the cardiac neurosis, with its various manifestations, seemed to be hyperexcitation of the sympathetic nervous system. The symptoms of irritable heart were abnormal precordial sensations; pain, sensitiveness, oppression; vasomotor symptoms (giddiness, flushes, dermographia, faintness); dyspnea (actual and subjective); extrasystoles producing subjective sensations; tachycardia following slight effort, constant tachycardia, and sudden changes of heart rate. The physical findings were a normal sized heart; thrill-like, split systolic impact and first sound over the mitral area; systolic murmur over the lower precordium, rapid regular heart; normal rate with occasional, extra systoles; sudden changes of heart rate; slow heart action with ventricular contractions. The etiological factors were previous history of shock or fright or emotional strain; reflex excitation from intestinal canal; physical fatigue with insufficient rest; insufficient recuperation following acute infections; disturbance of the organs of internal secretion (thyroid, adrenals, etc.). Having shown the close etiological and symptomatic relation between the irritable heart in general and military practice, he stated that in the latter, tachycardia, especially following effort, was the most common sign and vasomotor symptoms alone were less common, while in general practice the vasomotor alone often predominated. It was to be emphasized and remembered that patients frequently complained of palpitation without tachycardia, that was, they had a subjective feeling of palpitation. In a few such instances he had been able to discover with the aid of the fluoroscope that such patients showed particularly strong ventricular contractions, the left ventricle being decidedly diminished in size with each systole. This might perhaps be the physical explanation of the subjective palpitation in some of these cases. Some of the patients gave definite histories of nervous taint in either parent, or in a closely related member of the family. The writer believed, however, that while such taints might be common, they were not the actual exciting or impelling causes. Some great emotion, fright, dread, or shock was usually the direct antecedent cause of the outbreak of the cardiac symptoms. Reflex excitation from the gastrointestinal canal was the next most frequent. In other words, the cardiac nerves of an hereditary neurotic individual apparently reacted more readily, more continuously, and in more exaggerated fashion to a neurotic "insult" than did those of an individual with normal poise. He believed the symptoms of hyperthyroidism, so-called, which were sometimes seen in these cases, could be explained on the basis of hyperirritability of the sympathetic nervous system. In speaking of the treatment the writer said that in the soldiers abroad this had narrowed itself to a comparatively short period of rest, and then graded retraining in camp routine; mild exercise at first, route marches, light packs, heavy packs, etc. In this way a fair proportion of these soldiers became fit for active duty. Digitalis was not found of any value as was a priori to be expected. In private practice these patients could be better individualized. He had found that if

after a careful examination patients could be assured that they had no heart disease, and that all the symptoms were the result of "upset nerves," the cure was tremendously hastened. An explanation, especially to intelligent patients, which was not too scientific, but which offered a sufficient cause for the symptoms, was also of distinct benefit. What patients dreaded most was sudden death; with a satisfactory explanation for their symptoms, they were usually relieved, sometimes permanently of this fear. Light exercise, such as billiards, croquet, bowling were excellent for purposes of mental relaxation as well as for increasing the amount of exercise. The object of treatment was re-education of the tone of the cardiac nerves in order to regain stability and this was often a slow and tedious process. Sharp sudden exercise was to be avoided. The doctor should never omit praise for good work on the patient's part in overcoming his timidity to exercise, despite the presence of minor symptoms. Medicinally, he had found mixed bromides and suprarenal gland extract the best drugs. His usual procedure was to give one gram of the mixed bromides, well diluted in water, three times a day after meals. In cases marked by sleeplessness, he added 10 grains of chloral hydrate or eight grains of veronal every night for a few nights, and had seen no bad effects upon the heart or upon the individual from these procedures. The suprarenal gland he prescribed in five grain tablets to be taken only when symptoms of tachycardia or precordial pain became annoying. Paradoxical as it might seem, he prescribed this extract even when hypertension was present. Its beneficial effect seemed to depend upon its power temporarily to stabilize and decrease vasomotor instability by its action on the vasomotor center, thereby counteracting the cause of many of the symptoms.

Dr. Alexander Lambert said that the ideas expressed in the paper fitted in with his experience in private practice and with what one saw in some of the soldiers abroad. It was true that in private practice they had for years seen a type of disturbance produced by fright in which the predominating influence was exerted on the heart, through the special function of the accelerator nerves or by some force that affected these nerves. He did not feel that the phenomena in these cases could be attributed entirely to the nerves but that there was often a force back of the nerves that was an etiological factor. What had interested him among the soldiers was that they did not all show the same type of this affection. There were several different types. One gave the idea of hyperthyroidism, while another gave the impression of hypothyroidism, and there was also an emotional type. There was still another curious syndrome of which Dr. Neuhof did not speak, and that was a peculiar blue-red discoloration of the hands and forearms, which gave the impression of Raynaud's disease. This peculiar blue-red tinge would reach from the elbows to the fingers. The hands did not seem warm or feverish, but cool. This edema did not go away and nothing that was done for it seemed to have any effect in making it disappear. Dr. Lambert said he had not had these patients under his personal care, but Major McNee had told him that necropsies had shown that the thyroids were three times their natural size; that instead of weighing 30 grams they weighed 100 grams. This was not necessarily a pathological enlargement but a defensive reaction, a physiological enlargement made necessary by the fact that the men were called on to furnish more of the force supplied by the thyroid. Many of these patients were men in whom the unwonted exertion and emotional strain under which they were living resulted in a loss of equilibrium in the endocrine systems. Dr. Neuhof was quite correct when he said that the patients came to consult a physician because they were frightened for fear of sudden death, the impression among the laity being that if they had symptoms referable to the heart the luxury of sudden death was being forced upon them, and the physician had to explain to them that this would not occur. Dr. Neuhof's viewpoint was accurate in correlating the conditions seen in private practice with those seen in soldiers.

Dr. Alfred E. Cohn said that the picture of these cases was such as Dr. Neuhof had described. The question arose as to whether they were to be withdrawn from consideration in the field of mechanistic phenomena and were to be included in that of neuropsychiatry. It seemed to be necessary to call attention to certain distinctions that need be made. The cases were not cardiac in origin. It had already been mentioned that the relation of these cases to hyperfunction of the thyroid gland was a vague conception as was likewise the association with the other glands of internal secretion. These possible associations must be considered and carefully weighed before it was decided that the syndrome represented a reflex to stimuli which were simply psychic in their origin. Major MacNee's observations on the thyroids probably did not obtain in all instances. This aspect of the subject required study because prophesying the outlook of the patient depended on the decision. It was important to understand the nature of the conditions for on this the type of therapy to be applied depended. To be able to judge of this one must consider all the possible underlying factors. If the affection was found to be due to a psychic insult, methods must be instituted directed toward the care of psychic disturbances. However, a proper therapeutic technique could be instituted only when the exact pathological physiology was understood. At the present time a ventilation of the problems connected with the subject was more important than to supply for it immediately a complete anatomy, a complete physiology, or a complete therapy.

Dr. E. Libman said he was at a meeting recently when these cases were discussed as they were seen in France. The speakers recognized that the same condition was seen in civil life. It seemed that the term neurocirculatory asthenia was the best available. As good a term would have been neurocirculatory instability, but if one recognized that asthenia always implied instability the terms became proctically identical He could speak of the disease only as he saw it in civil life. In such cases the vasomotor factor was often much more important than the cardiac disturbance. Some of the causes of this condition Dr. Neuhof had mentioned. The question was much more complex than it would seem at first sight. Drs. Oppenheimer and Rothschild had pointed out in their publication there was often a deficient nervous system to begin with. Besides that there were various causes in people with or without lowered resistance which were factors in bringing on the definite disturbance. A number of people who had lowered resistance and were asthenic, had, as shown by Stiller, gastroenteroptosis, loose tenth rib, and other stigmata. These people could often be picked out by having them look straight forward and observing whether the white sclerotic could be seen between the lower border of the cornea and the lower lid. As a rule if such a phenomenon was present the tenth rib would be found to be loose. In some cases the ductless glands were a factor in producing the condition as were also a mild tuberculosis, anemia, repeated childbirths, or other exhausting conditions. Accessory sinus disease, especially sphenoidal sinus disease, could bring on the condition. Gastric disturbances, with or without elevation of the diaphragm, might be exciting factors, and psychic troubles could act in the same way. When we considered these and other possible causes it was evident that the treatment was not a simple matter. Neurocirculatory asthenia or instability was not the complete diagnosis. Having reached this point, it was necessary to find out the cause of the asthenia, and in civil life this was more difficult than in the army. The treatment would have to be directed to whatever cause was found.

Dr. Foster Kennedy said he felt very strongly that Dr. Neuhof had helped them by stressing the identity of irritable heart in military and civil practice. He thought we would be more clear-eyed if it were emphasized that the cardiac symptoms were but the tail of the kite, the showy part of the machine; that almost all cases of the D. A. H. (disordered action of the heart) occurred in neurotic individuals. The soldiers who showed this syndrome, before they were subjected to the ordeal of battle or disease were unstable nervously and the nervous instability appeared before the cardiac symptoms. Before a man began to complain of cardiac symptoms there had been in most cases a removal of the normal which prevents a man from showing that inhibition, he had made up his mind that he was not

going into the line again; at any rate his morale was weakened before he developed heart symptoms. There was very definite evidence of undue sensitiveness to psychological stimulation in these cases. The wonder was that the human machine had stood the strain as well as it had done. It would be strange if the endocrine balance were not disturbed by the strain of war. He had had the opportunity of confirming the frequency of increased thyroidal activity. He had seen three men whom he knew to have been under great emotional stress and they had persistent tachycardia, shortening of the diastole, a very rapid pulse, and a constant diarrhea. In two the hair stood up straight for ten days after the insult. He did not know whether such observations had been made before, but there were many witnesses to the fact that the lay of the hair in both these instances was altered. The influence of the sympathetic nervous system on the physiological functions was illustrated by the fact that in his own camp when enemy air raiders were sighted nearly every man went immediately to the latrine. He had had his own personal experience when a 200 bomb fell near him and failed to explode. His pulse became irregular and increased in rate for two days. He was very much frightened just at the time as he had had no warning whatever, but the conscious fright did not last four minutes, while his heart continued to beat rapidly for two days. To what was this due after the mental effect had passed away? Even though these symptoms were caused by the mind we had to deal with the heart condition. We had to control the results of mental stimuli and this would have to be done by applying psychological remedies to psychological ills. They had been unable to control the affection by drugs and endocrinological methods had likewise been ineffective; we must needs apply psychological remedies; in emphasizing this idea Dr. Neuhof had done good service.

Dr. J. Milton Mabbott said he had served throughout the draft, as medical member of a local board, and saw many of these cases. This experience had given him some idea of the modus operandi which brought about the symptom complex. He thought the reader of the paper was quite right in referring to the sympathetic nervous system, but Dr. Kennedy had added the needed note in regard to the necessity for psychological control. He thought the need of a physical basis for the mental action had been given too little emphasis. If they would go back to physiology they would recall that when they divided the sympathetic on one side, there would immediately result a congestion and hyperemia on that side, and then by stimulation of the distal portion of the severed nerve one could cause the disappearance of the hyperemia. The effect upon the heart and circulation from division and stimulation of the pneumogastric nerve was equally interesting. The cerebrospinal system must be taken into account. If one had really seen a true case of nervous prostration, or of so-called anxiety neurosis, he would observe that the mental anxiety which was constant had an influence on the brain. In the war there was the instinctive idea of self preservation that made itself felt even in men of great courage so that when they went forward it was with great anxiety which had an effect on the blood pressure. If one stopped to consider, at each complete contraction the heart threw out two ounces of blood into the aorta and if it failed to contract completely it would have to increase the rate to throw out a sufficient quantity of blood. So if there was a pulse rate of 120 to 160 it would mean that the heart was only contracting one-half or two-thirds as much as it should contract. A weak or frightened heart might fail to contract completely, and this might be due to the subconscious mental condition, aggravated at times by conscious fear and anxiety. Here the physician might help them out. The war was over, but one lesson of the war was that every one of these men should have been excluded from service in the Army, and had this been done perhaps there would not have been such great opportunities to study this subject and so many contributions to its literature. The condition was studied in the Civil War. So far as the name was concerned he thought the English term irritable heart was probably as good for ordinary use as neurovascular asthenia, but the latter term more nearly covered the general exhaustion of the nervous system and the psychological and psychopathic status present in these cases.

Dr. Neuhof, in closing, said that in view of Dr. Libman's remarks with reference to constitutional types he wished to emphasize the fact that he did not find anything which he could correlate with constitutional inferiority. He could not confirm that the enteroptotic type was more prone to develop the irritable heart than others. In his paper he had mentioned that he had regularly studied fluoroscopically the diaphragmatic excursion and he had never been able to discover that elevation of the diaphragm had any correlation either to the advent of the syndrome or its continuance. Many of the patients had broad, flat-lying hearts but he could not determine that the condition was more frequent among such individuals than among others. Dr. Neuhof said he did not care to quarrel about names. In war practice there might be good reasons for diverting attention from the heart, but in private practice no such reasons existed, particularly if one explained to the patient that the symptoms of which he complained were not due to actual heart disease. It would be difficult in private practice to avoid speaking of the heart since it was just the symptoms apparently referable to the heart that attracted the patient's attention constantly. It was therefore better to reassure the patient, explain the situation, and get his cooperation.

The Infection of Streptococcus Viridans and Its Clinical Picture.—Dr. Heinrich F. Wolf presented this communication in which he said that in the diagnosis of disease our laboratory methods had assumed such a part in our examination that the study of the clinical picture had been neglected. In this paper it was the writer's aim to show that the study of the clinical picture was of vital importance and for the sake of brevity he would confine himself to the so-called rheumatic manifestation of *Streptococcus viridans* infections with the exclusion of the endocarditis. A case was reported to show that there was a possibility of differentiating between the various forms of infectious arthritis on the basis of the clinical picture in spite of an adverse biological reaction. The number of patients who were treated with gonococcus vaccine for a rheumatic affection and whose disease had nothing to do with that infection was very large. As he could not admit unconditionally the claim of many physicians that a non-specific vaccine was just as good as a specific one, he regretted this practice of mixing up the etiology. All had seen many patients whose teeth had all been extracted without the slightest effect on the disease, and this fact alone would justify an attempt to solve the problem. He thought it would help in the solution of the problem if they could agree on the question, whether the fact that an individual was suffering from a pathological condition commonly classed as rheumatic was an indication that microorganisms had entered the system. Was every case of this type due to bacteriemia or did cases exist in which the toxin had merely entered the circulation and produced the symptoms? On purely clinical grounds he could not concede that a large number of such pathological conditions could be caused by bacteria in the tissues. He had observed often that an excruciating pain in the region of the shoulder bursa or a brachial nerve plexus which had lasted for days had ceased an hour or two after the extraction of a tooth. In consequence one could believe in a metastatic infection. Years ago he advanced the theory that the focal infection from which an attack of rheumatism originated first threw merely toxins into the circulation which, as one would say now, produced pathological changes through their chemical affinity. In the course of the disease the barriers between the focal infection and the entire system broke down and the organism entered the general circulation. This conception, to his mind, bridged the difference between the various authors and explained the changes in the clinical picture. Furthermore, their understanding had been aided by the works of Rosenow in which he proved the acquired affinity of certain strains of microorganisms. The most frequent seats of the *Streptococcus viridans* infections in monarthritis were the knee joint, the foot, the bursa subacromoidalis, and the hand. He had never seen a monarthritis which he could trace to an infection with colon bacillus, pneumococcus, or staphylococcus. One of the most frequent manifesta-

tions of *Streptococcus viridans* infection was the acute bursitis subacromoidalis, which he found in at least 75 per cent. of the cases of infected teeth or tonsils, and even where the disease followed an injury he had the impression that the injury was only the exciting cause. The borderline between the monarticular and polyarticular forms of *Streptococcus viridans* infection on the one side and between the toxic form and the metastatic form on the other was not sharp but only artificial. However, he could not believe that all the cases were due to metastasis or that they began as such. One of the earliest symptoms of *Streptococcus viridans* infection was a severe pain in the finger joints at night or toward morning. It might disappear in a few seconds and there were no objective signs to be seen. This symptom might last for months before any other sign appeared. In this stage one could keep the pain under control by salicylates. The clinical picture might show a great variety of forms dependent on the fact that some joints might be affected by toxins only and the others by toxins and the organisms. When the disease progressed there were marked changes in the capsule and bursæ. One of the essential differences between the infection with *Streptococcus viridans*, on the one hand, and the infection with the gonococcus and colon bacillus and the *Spirochæta pallida*, on the other, was the inefficacy of the salicylates in the latter, though they might not be effective in every case of *Streptococcus viridans* infection. If after the use of salicylates the pain stopped only temporarily one could exclude the organisms of the three latter infections. Polyarthritis of gonorrheal origin was a purely toxic form. The joints which were most frequently affected were the knee joints, interphalangeal joints, and the elbow and wrist joint. The swelling was strictly interarticular, developed quickly, and did not cause much pain. The amount of synovial fluid changed quickly, and a joint which was very swollen one day might be much better the next, while another joint would be swollen. There frequently occurred a periostitis of the spur of the calcaneus. The infection with the colon bacillus was characterized by a peculiar change in the skin of the fingers and a peculiar blood picture. Luetic arthritis was characterized by the mildness of the subjective symptoms. The joints most affected were the interphalangeal joints, but the swelling was strictly interarticular. There was no tenderness of the spur of the calcaneus. It seemed impractical to establish a definite identity for staphylococcus and pneumococcus infection, but he thought a thorough study of such cases would give the clue. The differentiation of an arthritis due to *Streptococcus viridans* and *Streptococcus hemolyticus* was rather difficult, though it seemed that the pain in *Streptococcus viridans* arthritis was not as severe or persistent as in *Streptococcus hemolyticus*. The writer summed up his idea by stating that we knew that infectious foci could exist in the body without causing symptoms. Abscesses in the teeth and tonsils might be found without giving rise to a systemic infection. A systemic infection might be present in spite of negative biological reaction. A positive biological reaction—for instance, a positive gonococcus complement fixation test—was no proof that a given disease was of the etiology which was indicated by the test. The value of the clinical picture in determining the etiological diagnosis of the so-called rheumatic disease had been grossly underestimated. As the clinical picture was due to the reaction of the body tissue against the invading and attacking organism, we might expect that it would vary according to the type of organism. In the case of tuberculosis of a joint the clinical picture was very generally accepted. The differences in the clinical pictures were not always very pronounced, but were distinct enough to allow a differentiation. The fact that these differences had been overlooked in their clinical work could probably be attributed more to the dulling eye and sense than to the lack of clear indications. We must not forget that a clinical picture might be due to a mixed infection and that each left its trace in the appearance of the disease.

Dr. E. LIBMAN stated that he had not attempted to make the clinical diagnosis of the bacterial causes of clinical arthritis, as Dr. Wolf had done, because he was not clear on many points. It was very important to be careful in using the term rheumatism. As soon as a local cause for a joint case was found, or there was present one of the common bacteria, it was already known that the case was not one of rheumatic fever, but was a case of arthritis and should be named according to the bacteriological cause. The etiological organism of rheumatic fever had not yet been isolated; an hemolytic streptococcus which had been found in cases of rheumatic arthritis was to be considered a secondary invader. For the identification of rheumatic fever we had only clinical criteria and post-mortem evidence. The post-mortem evidence consisted in a definite type of endocarditis and the presence of Aschoff bodies in the heart muscle. When the virus of rheumatic fever was once found, a serological test would probably be available. It was interesting to note that the absence of bacteria from the joint did not prove that the case was not bacteriological in nature. He had seen a couple of cases in which there was secondary infection of the joint with hemolytic streptococci in the blood, and still one could find turbid fluid and no or very few bacteria by culture. There might be organisms enclosed in leucocytes and usually they could not be cultivated. In such cases the bacteria might probably be found visible in the bone or periarticular structures. It was a curious fact, in view of the supposed frequency of joint conditions secondary to local foci caused by the presence of *Streptococcus viridans*, that there was no progressive arthritic disease in cases of endocarditis due to the same organism. Dr. Libman stated that he had seen at least 250 cases of that type of endocarditis and he had never seen anything but transient involvement of the joints. It was strange that there should be such marked disorders in the joints from small foci of infection and in endocarditis cases with bacteria in the blood for months there should be no marked involvement of the joints. It was not safe to say that a local streptococcus infection was the cause of a joint involvement unless a positive complement fixation test was found. Even then it could be possible that the complement fixation test was due to the presence of the local infection and the joint disease might be due to some other cause. As regarded the colon bacillus, it was very doubtful about its playing a rôle in joint infections. He believed the overgrowing of the colon bacilli in the large intestine by anaerobes might help in the production of joint disorders. He stated that too much stress had been laid on infections of the teeth and tonsils, in many cases, which were due to other causes. He had seen tonsils and teeth removed in cases of straightforward gout. Besides the joint diseases due to gout and other metabolic disorders, there were joint involvements due to tuberculosis and ductless gland disturbances and to scleroderma. It was important to remember that a joint disease could be due to more than one cause. The patient might have his joint sensitized by a metabolic disorder and the actual disease brought on by infection, or the reverse might happen. It stood to reason that where infected tonsils or teeth were present they should be treated, because known foci of infection should not be allowed to be present in the body. If the patient, however, was suffering from a severe illness and it was clear that these local foci were not the cause of the trouble, their eradication might be attended to at a later time.

Dr. GEORGE ROBERT ELLIOTT said that Dr. Wolf's paper had given them a clinical picture of the *Streptococcus viridans* in joint action, from which he was able to recognize some of the forms. In discussing the paper he wished to confine his remarks to only one phase of the paper. Dr. Wolf had said that he believed the organism caused the arthritides in one of two ways: either through the action of the toxins or through the infectious organism forming a metastasis. Dr. Elliott believed there was a third way in which the organism might act. The *Streptococcus viridans* illustrated the three ways perhaps better than most germs. Lying in a closed cavity, being anaerobic, a point often lost sight of, it generated its toxins and these, thrown out into the blood current, produced a chain of symptoms of an irritative nature. Just how much damage could be done was not known. Secondly, the organism might pass into the circulation directly and through metastatic action set up an articular process, the organism retaining its virulency. We were familiar with the Neisser bacillus

in this kind of action. Retaining its pus-producing power, it not infrequently produced suppuration. The *S. viridans* might act similarly. Dr. Wolf had called attention to its action in acute acromial bursitis. There was a third way this organism might act. No explanation had yet appeared of this mode of action better than Rosenow's, that the organism lying in its enclosed cavity acquired a selective affinity for a joint and lost its pus-producing power. Entering the circulation, it localized itself in the vicinity of a joint, not in the joint cavity, as had been stated tonight—the joint cavity being almost invariably sterile—set up the complex pathological picture with which we were familiar: the pannus formation, thickened synovial membrane, loss of cartilage, loss of bone, together with secondary tissue changes. This threefold view gave us a rational clue as to treatment. It explained why we got results and why we did not. If toxins alone were acting, then removal of the point of focal infection would cure our patient. Just as symptoms were relieved by rendering the intestinal tract aseptic and preventing the absorption of deleterious substances. If the organism had been thrown into the blood channel in all its virulency then a local process was set up, and we did not always get a cure by removing the local site. We have to treat the local arthritis; sometimes, as in Neisser affection, to open and drain the joint. If the organisms were acting in the third manner—that is, having acquired a new life and growing independently of their original focal point— we saw why we got so little result from removal of the focus. We saw tonsils removed and the wholesale removal of teeth with no benefit. It was in this field that the subject had been so frequently discredited. Just how far these organisms could go on acting was not definitely fixed. In certain cases the time seemed limited. In others the action was continued a long time. In our older cases, as a rule, our treatment brought the result of repair only, just as after poliomyelitis. We were dealing with damage done. A logical clinical diagnostic conception thus gave a logical basis for treatment.

Dr. Wolf, in closing, said he thought Dr. Elliott must have misunderstood him when he stated that nothing was said in reference to the action of the gonococcus in joints and that he had only distinguished between the toxic form and the metastatic form. He had purposely avoided the term rheumatism or going into the etiology connected with that term. Arthritis due to the colon bacillus was very rare. As Dr. Libman had pointed out, there were so many causes of arthritis that naturally in a brief paper he could not differentiate every possible form of arthritis. It was quite plain that the gouty form of arthritis was quite different from the forms he had discussed, but clinically one could not always differentiate the mild forms. The paper was not to be considered as exhaustive, but was presented merely to call attention to the possibility of differentiating some forms of arthritis clinically. The problem was not solved, but there was a possibility that a solution might be reached through cooperation.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK

New York, May, 1919.

ANATOMY.

1. Describe the nasal cavity or nasal fossa (cavum nasi).
2. Give the origin and the insertion of each of the following muscles: (*a*) the pectoralis major, (*b*) the rectus femoris, (*c*) the masseter.
3. Describe the thoracic duct (ductus thoracicus).
4. Give the course, relations and branches of the femoral artery (arteria femoralis).
5. Give the formation, course and distribution of the median nerve (nervus medianus).
6. Describe the structure and the minute anatomy of a vein.
7. Give the gross anatomy and the relations of the pancreas.
8. Describe the mesentery (mesenterium).
9. Give the boundaries of the third ventricle of the brain (ventriculus tertius).
10. Give the position and relations of the heart.
11. Describe the ovary (ovarium) and the Fallopian tube (tuba uterina).
12. Name the structures that would be divided in a section through the middle third of the leg.

PHYSIOLOGY.

1. What information is obtained from an examination of the pulse?
2. What is meant by metabolic equilibrium?
3. From what portions of the cortex cerebri do the arm, face, and leg receive their motor impulses?
4. Describe (*a*) forced expiration, (*b*) a method of artificial respiration.
5. What is the poisonous gas from incomplete combustion that, when inhaled, causes asphyxiation? What is the effect of this gas on hemoglobin?
6. Describe the structure and the development of adipose tissue.
7. Is it beneficial or harmful to drink water with meals? Give a physiologic explanation of your answer.
8. Does injury to the motor tracts of the pyramids cause complete atonic paralysis of the area supplied by the affected fibers? Explain.
9. Describe the function of the vocal apparatus in the production of musical tones.
10. With what physiological function are the bipolar cells associated?
11. Describe fully the function and the control of the urinary bladder and the sphincter vesicæ.
12. Describe the abnormal conditions that cause subjective sensations of sound in the ears.

CHEMISTRY.

1. Distinguish chemically between milk sugar and cane sugar.
2. What acids are found in the bile? How would you test for the presence of acids in the bile?
3. How may chlorine be prepared? Give the properties of chlorine.
4. Give the general properties of enzymes.
5. What is gelatin? Discuss the value of gelatin as a substitute for protein foods.
6. Discuss the action of bichloride of mercury as a poison. What means should be taken to inhibit its action?
7. How is chloroform made synthetically? What impurities in chloroform render it unfit for an anesthetic?
8. What is the chemical composition of muscle tissue?
9. Discuss Dakin's solution, giving its composition and its chemical action on the tissues.
10. Discuss enzymes as catalytic agents.
11. Give the chemical changes taking place in carbohydrate from its ingestion as starch to its storage in the liver as glycogen.
12. What is the significance of creatinine in the urine? How may the amount be increased?

ANSWERS.

ANATOMY.

1. The *nasal fossæ* are two irregular cavities situated in the middle of the face. They open in front by the anterior nares, and behind into the nasopharynx by the posterior nares. They are separated by the septum, which is generally deviated to one side. The mucous membrane lining the nasal fossæ is called the Schneiderian membrane. Each fossa has a roof, a floor, an inner and an outer wall. From the outer wall there project into each fossa the superior and middle turbinated processes of the ethmoid bone, and the inferior turbinated bone; these bony processes divide each fossa into a superior, middle, and inferior meatus. The nasal fossæ communicate with the sphenoidal sinus, the anterior and posterior ethmoidal cells, the frontal sinus, and the antrum of Highmore.

The *roof* is formed by the ethmoid, nasal, frontal, sphenoid, vomer, and palate bones; the *floor* is formed by the maxillary and palate bones; the *outer wall*, by the nasal, maxillary, lacrymal, ethmoid, inferior turbinated, palate, and sphenoid bones; the *inner wall*, or *septum*, by the ethmoid, vomer, frontal, nasal, sphenoid, maxillary and palate bones, and septal cartilage.

2. PECTORALIS MAJOR.—*Origin:* Anterior surface of inner half of clavicle, anterior sterno-clavicular ligament, half of anterior surface of sternum, and anterior surface of upper six costal cartilages. *Insertion:* The outer bicipital ridge of the humerus.

RECTUS FEMORIS.—*Origin:* Anterior inferior spine of ilium and anterior part of the dorsum ilii just above the brim of the acetabulum. *Insertion:* The anterior part of the upper border of the patella.

MASSETER.—*Origin:* The lower border and internal surface of the zygomatic arch. *Insertion:* Outer surface of the ramus of the lower jaw, also the angle and coronoid process of the same bone.

3. The *thoracic duct* extends from the second lumbar vertebra, where it commences by a dilatation, the *receptaculum chyli*, to junction of left internal jugular with left subclavian vein. The abdominal part is placed on the front of the body of the second lumbar vertebra, behind and to the right side of the aorta and on the inner side of the right crus; it then enters the thorax through aortic opening, on the right side of the aorta, lying between it and the vena azygos major, and passes upward to right of aorta on right of intercostal vessels. Opposite the fourth dorsal vertebra it passes to the left behind arch, and runs along the left side of the esophagus, behind the left common carotid artery. At the level of the seventh cervical vertebra it turns outward and, passing behind left internal jugular and crossing first part of left subclavian artery, arches over the apex of the left pleura to open at the angle of union of the left internal jugular and left subclavian veins.—(From *Aids to Anatomy.*)

The *portions of the body drained by it* are: Both lower limbs; abdomen, except upper surface of the liver; left half of thorax; left side of head and neck, and left upper extremity.

4. FEMORAL ARTERY.—*Course:* It is the direct continuation of the external iliac; it begins behind Poupart's ligament, passes down the front and inner part of the thigh through Scarpa's triangle, and terminates at the opening in the adductor magnus, where it becomes the popliteal artery. Its *branches* are: Superficial epigastric, superficial circumflex iliac, superficial external pudic, deep external pudic, profunda femoris, muscular, and anastomotica magna. By means of these various branches it *is distributed to:* Superficial inguinal glands, skin, and superficial fascia of the inguinal region, penis and scrotum (or labia majora), perineum, flexor muscles on the back of the thigh, the adductor muscles of the femur.

Relations: Superficial in upper third, being contained in Scarpa's triangle, more deeply placed in middle third (Hunter's canal). In first 1½ inches is enclosed in femoral sheath. *In front:* Skin, superficial and deep fascia, internal cutaneous branch of anterior crural nerve, sartorius, long saphenous nerve, aponeurotic arch over Hunter's canal. *Behind:* Psoas, profunda vessels, pectineus, adductor longus, femoral vein (at lower part of Scarpa's triangle, and in Hunter's canal), tendon of adductor magnus. *Inner side:* Femoral vein (in Scarpa's space), adductor longus. *Outer side:* Sartorius (in Scarpa's space), vastus internus, femoral vein gets to outer side near ending.—(From *Aids to Anatomy.*)

5. The *median nerve arises* by two roots, one from the outer cord, the other from the inner cord of the brachial plexus. It passes down the middle of the anterior surface of the arm and forearm to the hand; at first it is external to the brachial artery, then it crosses it, and then it lies on the inner side of that artery; it lies behind the bicipital fascia at the elbow, and passes into the forearm between the two heads of the pronator radii teres, and descends the forearm between the flexor sublimis and flexor profundus digitorum.

Its *principal branches* are the muscular, anterior interosseus, palmar cutaneous, muscular (to the thumb), and digital branches.

It is distributed to all the superficial muscles on the front of the forearm except the flexor carpi ulnaris; all the deep muscles on the front of the forearm except the inner half of the flexor profundus digitorum; the skin over the palm of the hand; the abductor pollicis, opponens pollicis, and the outer head of the flexor brevis pollicis; the outer three and a half fingers, and the first and second lumbricales.

6. *Veins* have three coats, arranged similarly to those of arteries: The tunica interna, or internal coat; the tunica media, or middle coat, and the tunica adventitia, or external coat. The internal coat consists of a basement membrane, on which is a layer of endothelial cells. The middle coat consists of involuntary muscle fibers, between the layers of which are some elastic fibers. The external coat consists of connective tissue (white fibrous and yellow elastic). Between the two outer coats is an elastic membrane. But in the *veins* the middle coat possesses less elastic and muscle tissue and more fibrous tissue, hence the tendency of veins to collapse when empty. In veins the external coat is the thickest; in arteries the middle coat is the thickest. Veins have valves, as a rule. Functions of the endothelial lining of the inner coat is to make a smooth surface for the circulation of the blood with as little friction as possible. The muscular fibers supply contractility. The elastic fibers supply elasticity. The connective tissue fibers supply strength and support.

7. The *pancreas* is long and irregularly prismatic in shape; it has been compared to a human or a dog's tongue. The right extremity is called the head, which fits into the curve of the duodenum; the left end is called the tail and reaches to the spleen. The stomach lies in front of the body of the pancreas, and the transverse colon and its mesentery cross the lower end of the head, which is also in relation to the superior mesenteric vessel. Behind the pancreas are the superior mesenteric artery and vein, portal vein, inferior vena cava, aorta, crura of diaphragm, left kidney with its suprarenal capsule. Below are the jejunum, the duodenojejunal junction, and the splenic flexure of the colon. Above the neck is the pyloric end of the stomach. The pancreas lies across the front of the first and second lumbar vertebræ, behind the stomach, and in the epigastric and left hypochondriac regions. Its canal is the duct of Wirsung, which extends transversely from left to right and opens into the duodenum in common with the ductus communis choledochus.

8. The *mesenteries* are peritoneal folds connecting any portion of the gastrointestinal tract to the posterior abdominal wall. The *mesentery proper* is a fan-shaped fold of peritoneum beginning at the spinal column and following and covering the anterior aspect of the superior mesenteric vessels to the loops of the small intestine, enveloping all the coils of the jejunum and ileum (but not those of the duodenum)—returning thence along the posterior aspect of the superior mesenteric vessels to the vertebral column. The root of the mesentery extends from the left lateral aspect of the body of the second lumbar vertebra donward—crossing obliquely the spinal column, aorta, vena cava inferior, and third portion of the duodenum, ending at the right sacroiliac synchondrosis, or in the right iliac fossa. It contains between its right upper and left lower layers, the mesenteric arteries and veins, lacteals, lymphatics, and nerves, all held together by fatty areolar tissue. . . . Its length is about 21 feet, its width averages 8 to 9 inches.—(From Bickham's *Operative Surgery.*)

9. BOUNDARIES OF THE THIRD VENTRICLE OF THE BRAIN: The *roof*, by the velum interpositum, suspending the choroid plexuses of the third ventricle, and *laterally* the peduncles of the pineal gland; *floor*, by the parts inclosing the interpeduncular space at the base of the brain, viz., the lamina cinerea, tuber cinereum and infundibulum, corpora albicantia, and the posterior perforated space; *laterally*, by the optic thalami; *in front*, by the anterior commissure and anterior crura of the fornix; *behind*, the posterior commissure and the iter a tertio ad quartum ventriculum.

10. The *heart* is located obliquely in the thorax, between the lungs, and enclosed in the pericardium. A line from the lower border of the second left costal cartilage (1 inch from sternum) to upper border of third right costal cartilage (½ inch from sternum) represents the *base line;* the *right side* will be a line drawn from right side of upper limit to seventh right chondrosternal articulation; the *lower limit* is a line from this last point to the apex (in fifth left intercostal space 3½ inches from mid-line); the *left side* from left end of upper border to left of apex. The heart lies opposite the fifth, sixth, seventh, and eighth dorsal vertebræ.

11. The *ovaries* are two in number, and correspond

to the testes in the male; they are of a flattened ovoid form, vertically placed in the posterior part of the broad ligament. By its anterior border the ovary is connected to the broad ligament, and by its lower pole to the uterus by a proper ligament, extending to the superior angle of the uterus, and called the *ligament of the ovary* The lateral surfaces and posterior borders are free. The superior pole and posterior border are embraced by the Fallopian tube; on its inner surface it is in relation with small intestine in Douglas' pouch, and externally lies in a peritoneal fossa between the external and internal iliac vessels as they diverge. The vessels enter the hilum at the attached anterior border. —(*Aids to Anatomy.*) The *arteries* are the ovarian, from the aorta; the *nerves* are from the ovarian plexus and the aortic plexus.

The *Fallopian tubes* are two in number, placed in the upper margin of the broad ligament. Each tube measures about 4 inches in length. The cavity commences by a narrow orifice called the *ostium internum*, and terminates in a *fimbriated extremity*, which passes over the superior and posterior borders of the ovary, and is attached by the fimbria ovarica to the superior pole of the ovary.—(*Aids to Anatomy.*)

12. The structures severed by amputation through the middle of the leg are: The skin; cutaneous vessels and nerves; aponeurosis; tibialis anticus, extensor longus digitorum, extensor proprius hallucis, peroneus brevis, peroneus longus, flexor longus hallucis, soleus, gastrocnemius, plantaris, flexor longus digitorum, and tibialis posticus muscles; anterior tibial artery veins and nerve; posterior tibial artery, veins and nerve; peroneal artery and veins; tibia, fibula, and interosseous membrane.

PHYSIOLOGY.

1. *Information which may be obtained by examination of the pulse:* The force, frequency, and regularity of the heart's action; the condition of the arterial walls; (approximately) the blood pressure can be noted. One can also observe if the pulse is small or large, and whether the wave rises and falls rapidly.

2. By *metabolic equilibrium* is meant that condition of the body in which the ingesta and egesta are equal, and in which there is neither gain nor loss of weight.

3. The motor area in the brain is that portion of the cerebral cortex situated immediately in front of the fissure of Rolando. It is the part concerned with the functions of muscular movement. At the upper part of this area are the parts connected with the movement of the lower extremities; then from above downward are located the centers for the movements of the trunk, shoulders, arms, wrists, fingers, face, lips, tongue, larynx, and pharynx.

4. *Forced expiration:* "After the elastic forces have ceased to act and the normal expiratory movement has been brought to a close, the thorax can be, to a considerable extent, still further diminished in all its diameters by the contraction, through volitional effort, of abdominal and thoracic muscles. To this decrease in the capacity of the thorax, as a result of which a much larger volume of air is expelled from the lungs than during passive expiration, the term *forced* expiration has been given. With the cessation of muscle activity the elastic forces of the now compressed thoracic walls, aided by the return of upward displaced abdominal organs, at once restore the thoracic walls to the position they had attained at the end of passive expiration. Of the muscles active in *forced* expiration in addition to the intercostales interni and the triangularis sterni, the following may be mentioned, viz., the *abdominales*, the *serratus posticus inferior*, and the *quadratus lumborum*. The conjoint action of these muscles is to diminish the convexity of the abdominal walls and to exert a pressure on the abdominal organs. These, taking the line of least resistance, are forced upward against the inferior surface of the diaphragm, which in consequence becomes more strongly curved and ascends higher into the thorax. The vertical diameter of the thorax is thus diminished. Acting from the pelvis as a fixed point, these muscles will also draw downward and inward the lower end of the sternum and the lower ribs and diminish the antero-posterior and transverse diameters."—(Brubaker's *Physiology.*)

Artificial respiration: "The method introduced by Schäfer is the simplest, least injurious, and most effective. The subject is laid on the ground in the prone position, with a thick folded garment under his chest. The operator kneels by his side or athwart him, facing his head, and places his hands on each side over the lower ribs. He slowly throws the weight of his body forward, and thus presses upon the thorax of the subject and forces air out of the lungs; he then gradually relaxes the pressure by bringing his body up again, but without removing his hands. This is repeated regularly at the rate of twelve to fifteen times a minute until normal respiration begins, or until all hope of restoration is given up."—(Halliburton's *Physiology.*)

5. The gas referred to is carbon monoxide, which readily unites with hemoglobin, forming carboxyhemoglobin; this latter is more stable than oxyhemoglobin, and if present in sufficient amount will produce asphyxia.

6. "*Adipose tissue* consists of small vesicles, *fat cells*, lodged in the meshes of areolar tissue. The fat cells vary in size, but of about the average diameter of $\frac{1}{500}$ of an inch. They are formed of an exceedingly delicate protoplasmic membrane, filled with fatty matter, which is liquid during life, but becomes solidified after death. They are round or spherical where they have not been subjected to pressure; otherwise they assume a more or less angular outline. These fat cells are contained in clusters in the areolæ of fine connective tissue, and are held together mainly by a network of capillary blood vessels which are distributed to them. The fat cells are formed by the transformation of connective-tissue corpuscles, in which small droplets of oil are formed; these coalesce to produce a larger drop, and this increases until it distends the corpuscle, the remaining protoplasm and the nucleus being crowded to the periphery of the cell."—(Gray's *Anatomy.*)

7. It was formerly taught that water should not be drunk with meals, because (it was urged) such a procedure resulted in diluting the gastric juice and that digestion would be delayed or inhibited. But it has now been proved that the drinking of water with meals stimulates the secretion of gastric juice, also that it causes inhibition of the growth of intestinal bacteria, that it produces an improved liver function, that it decreases intestinal putrefaction, and that it enables the food to be utilized more economically; further, the saliva acts more efficiently as an amylolytic agent when diluted with water. For all these reasons we may infer that it is beneficial to drink water with meals.

8. "With regard to the musculature of the limbs especially a difference has been observed in the paralysis caused by injury to the spinal and pyramidal (cerebrospinal) neurons, respectively. Lesions of the anterior root cells in the cord or of the axons arising from them cause complete paralysis of the corresponding muscles, since these muscles are then removed not only from voluntary control, but also from reflex effects. The muscles are entirely relaxed and in time exhibit a more or less complete atrophy. When the pyramidal neurons are affected, as in the familiar condition of hemiplegia resulting from a unilateral lesion of the motor cortex, there is paralysis as regards voluntary control, but, the spinal neuron being intact, the muscles are still subject to reflex stimulation through the cord, especially to the so-called tonic impulses. Under these conditions, especially if the lesion is in the cord, it is frequently noticed that the paralyzed muscles are thrown into a state of continuous contraction, contracture, in which they exhibit a spastic rigidity. This fact, therefore, may be used in diagnosing the general location of the lesion. A satisfactory explanation of the cause of the tonic contraction has not been furnished. It may be due to uncontrolled reflex excitation of the spinal neurons or to the action of the indirect motor path by way of the rubrospinal tract."—(Howell's *Physiology.*)

9. "Voice is a musical note produced by the vibration of the vocal cords of the larynx and modified in character by the resonating chambers formed by the upper respiratory passages, the mouth, the accessory sinuses of the nose, and the chest. The vocal cords are thrown into vibration by the expiratory currents of air from the lungs. . . . When a note is produced the vocal cords are brought close together, and an expiratory current of air causes them to vibrate. The current of air must have a certain pressure, and this is produced by contraction of the muscles of the thorax

and abdomen which are concerned in expiration. The note produced may vary in loudness, pitch, and quality or timbre. The degree of loudness varies with the force of the expiratory current. The pitch is determined partly by the length and partly by the tension of the vocal cords. In children the pitch is relatively high, because the cords are short. At the time of puberty the larynx increases considerably in size, more so in the male than in the female, and as a result a boy's voice "breaks," that is, becomes much lower in pitch. The possible variation in pitch in any individual is on an average about two octaves. This is mainly due to variations in the tension of the vocal cords brought about by the reciprocal action of the cricothyroid and thyroarytenoid muscles. The pitch is also affected by the length of the vocal cords free to vibrate, this being determined by the movements of the arytenoid cartilages. Further, the force of the expiratory current influences the pitch, the stronger the blast of air the higher being the note produced. The quality of the note is due to the resonance produced in the various resonating chambers, the air in the chest vibrating with the lower notes, and that in the mouth and pharynx and in the accessory sinuses of the nose with the higher pitched notes. Hence the terms chest notes and head notes used in connection with singing."—(Bainbridge and Menzies' *Essentials of Physiology.*)

10. *Bipolar cells* belong to sensory neurons.

11. "When the urine has passed into the bladder, it is there retained by the sphincter vesicæ muscle, kept in a state of chronic contraction by the action of a nerve center in the lumbar region of the spinal cord. This center can be inhibited and the sphincter relaxed, either reflexly, by impressions coming through sensory nerves from the mucous membrane of the bladder, or directly, by a voluntary impulse descending the spinal cord. When the desire to urinate is experienced impressions made upon the vesical sensory nerves are carried to the centers governing the sphincter and detrusor urinæ muscles and to the brain. If now the act of urination is to take place, a voluntary impulse originating in the brain passes down the spinal cord and still further inhibits the sphincter vesicæ center, with the effect of relaxing the muscle and of stimulating the center governing the detrusor muscle, with the effect of contracting the muscle and expelling the urine. If the act is to be suppressed, voluntary impulses inhibit the detrusor center and possibly stimulate the sphincter center."—(Brubaker's *Compend of Physiology.*)

12. *Abnormal conditions that may cause subjective sensations of sound in the ears:* "Among the many causes which produce this one condition are alteration in the blood stream to the ear, anemia, intercranial aneurism, alteration in the calibre of the blood vessels of the ear, the direct influence of toxins upon the labyrinth and middle ear, osteosclerosis, and such diseases as mumps, scarlet fever, typhoid fever, malarial fever, diabetes, rheumatism, gout, etc."—(Kyle's *Diseases of Ear, Nose and Throat.*)

CHEMISTRY.

1. *Milk sugar* reduces Fehling's solution, readily undergoes bacterial fermentation with production of lactic acid, is soluble in 6 parts of cold and 2.5 parts of boiling water, forms an osazone with phenylhydrazine.

Cane sugar does not reduce Fehling's solution, does not undergo alcoholic fermentation until it has been split up into glucose and fructose, is entirely soluble in water, forms no osazone with phenylhydrazine.

2. *Acids found in the bile*, are: Taurocholic and glycocholic acids (as a rule, the salts of these acids are found); also, taurocholeic and glycocholeic acids.

Pettenkofer's test for bile acids: Place 5 c.c. of diluted bile in a test tube; add five drops of a 5 per cent. solution of sucrose. Run about 2 or 3 c.c. of concentrated H_2SO_4 carefully down the side of the tube; a red ring will appear at the point of contact, and on agitating the tube the whole solution becomes reddish. The tube must be cooled in running water.

3. *Chlorine may be prepared* by heating manganese dioxide with hydrochloric and nitric acids:

$$MnO_2 + 2HCl + 2HNO_3 = Mn(NO_3) + 2H\,O + Cl_2.$$

Properties of chlorine: It is a greenish-yellow gas, about two and a half times heavier than air; it has a penetrating odor and is very irritating to the respiratory passages; it is soluble in water; is a bleaching and disinfecting agent in the presence of water; it has a great tendency to combine with other elements.

4. *General properties of enzymes:* They are soluble in water, in glycerol, and in dilute salt solution; they are precipitated by alcohol and by ether; they work best in a temperature of about 40° C., but there are exceptions, each enzyme having its own optimum temperature; each enzyme has a very limited action, being specific for one substance only; each enzyme will work only in a medium of definite reaction, either alkaline or acid; and the products of their activity must be removed. When these conditions are fulfilled, enzymes are capable of doing a large amount of work.

5. *Gelatin* is a protein substance, being a collagen; it is amorphous, yellowish, hard, and brittle. It is produced by boiling collagen with water. It sets into a jelly when a solution made with hot water cools. It gives the xanthroprotein and biuret reactions, but not the Millon or Adamkiewicz reactions.

Gelatin as a substitute for protein foods: "There are some proteins which contain all the amino-bodies requisite for the maintenance and growth of the animal body and which have been designated, therefore, as "adequate proteins." There are others which are sufficient for a maintenance metabolism, that is to say, suffice to furnish material for the energy needs and for the repair of tissue waste, so that the animal does not lose in weight, but are not adequate for the purposes of growth in young animals, and, finally, there are some which when given as the sole protein food are not sufficient either for maintenance or growth. On a diet of this latter variety of protein the animal loses flesh and will eventually die. Proteins of this kind may be designated as "inadequate proteins." It has long been known that gelatin is an inadequate protein in this sense. It is digested easily and absorbed, and eventually undergoes oxidation in the body with the production of carbon dioxide, water and urea. The energy liberated by this metabolism is utilized no doubt in the body, and the gelatin constitutes an "energy food" similar in a general way to the carbohydrates and fats, although its various amino acids must give it to some extent a special significance. The important point in this connection is that gelatin alone or with carbohydrates or fats does not suffice to maintain nitrogen equilibrium. It does not supply fully the nitrogenous material needed for the repair of tissue. This deficiency is explained by the fact that in the composition of the gelatin certain important amino-acids are lacking, tryptophan, tyrosin, and cystein."—(Howell's *Physiology.*)

6. *Bichloride of mercury* has a corrosive action by virtue of its tendency to unite with protein bodies; and, when absorbed, it produces poisonous effects. The *symptoms of the poisoning* are: A burning pain in the mouth, pharynx, and stomach; the mouth and tongue are white; the vomitus is white, with shreds of mucous membrane, and tinged with blood; bloody stools; also salivation may occur. *Treatment:* The antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

7 *Chloroform is made* by the action of bleaching powder upon acetone:

$$2CO(CH_3)_2 + 6CaCl(OCl) = 2Ca(OH)_2 + Ca(CH_3COO)_2 + 2CHCl_3.$$

Impurities which render it unfit for an anesthetic: Chlorine, aldehyde, hydrochloric acid, and carbonyl chloride.

8. *Chemical composition of muscle tissue:* Water, about 75 per cent., and solids, about 25 per cent. The solids include proteins (myosinogen, paramyosinogen, myoglobulin, myoalbumin, nucleoprotein, myohematin, and collagen), carbohydrates (dextrose and glycogen), fats, extractives (xanthine, hypoxanthine, creatine, sarcolactic acid, and inosite), and inorganic salts (chiefly potassium phosphate).

9. *Dakin's solution* is a solution of sodium hypochlorite, containing not less than 0.4 per cent. and not more than 0.5 per cent. of NaClO; the solution must not be alkaline to powdered phenolphthalein, but must be alkaline to alcoholic solution of phenolphthalein. If the percentage of sodium hypochlorite is less than 0.4,

the antiseptic powder of the solution is too low; if it is more than 0.5, it is too irritating. If the solution is alkaline to powdered phenolphthalein, it is too irritating; and if it is acid to alcoholic solution of phenol, the solution is unstable.

Dakin's solution has practically no action on living tissues, but it dissolves necrotic tissues and destroys bacteria even in the presence of pus and bloody serum. The solution must come into immediate contact with the tissues; that is, into direct contact with every part of the actual wall of the wound.

10. *Catalytic action of enzymes:* "The analogy of enzymic action is so close to that of inorganic catalysts that the view at present current regarding it is that the action is a catalytic one. That is to say, the presence of the enzyme induces a chemical reaction to occur rapidly, which in its absence also occurs, but so slowly that any action at all is difficult to discover. To use the technical phrase, its action is to increase the *velocity* of chemical reactions. It is, for instance, quite conceivable that, if starch and water were mixed together, the starch will in time take up the water and split into its constituent molecules of sugar. But an action of this kind would be so slow, occupying perchance many years, that for practical purposes it does not take place at all. If an inorganic catalyst is added, such as sulphuric acid, and the temperature raised to boiling point, the action takes place in a few minutes; if an organic catalyst, such as the enzyme ptyalin, is added, the velocity of the change is even greater; but what is of more importance for the well-being of the animal, a moderate temperature, namely, that of the body, amply suffices. The organic catalysts or enzymes are, however, colloidal in nature (possibly protein), and this explains their destructibility by high temperatures."—(Halliburton's *Physiology.*)

11. Cooked starch is acted upon in the mouth by two enzymes of the saliva, ptyalin and maltase; the ptyalin converts the starch into maltose, and the maltase converts maltose into glucose. The intermediate stages between starch and maltose are the following: Starch is converted into soluble starch, this into erythrodextrin, this into achroodextrins, these latter into isomaltose and maltose. In the small intestine the amylopsin of the pancreatic juice acts like the ptyalin did, hydrolyzing the starch to maltose through the intermediate stages of dextrin and isomaltose. The maltose is converted into glucose, which is diffusible through the wall of the intestine, and is absorbed and passes into the circulation by way of the portal vein. In the liver the glucose is converted into the polysaccharose glycogen.

12. *Creatinine* occurs constantly in the urine, about one or two grams being excreted daily. The quantity excreted bears no relation to the amount of protein ingested. It is an end product of the metabolism of living protein rather than of food protein. It is *increased* in fevers, diabetes, exophthalmic goiter, in conditions in which muscle tissue is wasted, cachectic conditions, and as a result of violent muscular exercise.

(*To be continued.*)

Pertussis Cured by Ether.—Audrin claims to have cured rapidly cases of whooping cough by the injection of sulphuric ether, pure, given every second day in doses of 15 minims up to the age of 10 months and after this period 30 minims. The injection should be intramuscular, given in the thigh and at the same point for succeeding injections. The stage of the disease is not given. Rarely is a fourth injection necessary.—*Le Progrès Médical.*

Spermatodiagnosis of Syphilis.—Two Argentine writers have reported in *La Semana Medica* a technique for the diagnosis of syphilis through peculiar deformities of the spermatozoids. A few drops of fresh semen are placed on a microscopic slide and exposed to the vapor of osmic acid in 1-100 solution until a slightly grey coloration is visible. The slide is now dried as in the examination of a blood smear. Next a mixture of aniline solution and some drops of alcoholic solution of gentian violet is added. An exposure of from 2 to 5 seconds is sufficient, after which the slide is washed in running water from half a minute to a minute.—*La Medicina Ibera*

Miscellany.

A Medical Hero of Guatemala.—A recent issue of *La Juventud Medica* of Guatemala is devoted largely to the memory of Dr. J. Antonio Villagrán, who succumbed to yellow fever while in the midst of a campaign of sanitation against that scourge. The deceased at the time of his death was editor-in-chief of the journal which is the official organ of the medical society of the same name. He was especially identified with the study of parasitology and his inaugural thesis had been devoted to the subject of the ileotyphlocolitis which is set up by the trichocephalus. This is said to be a masterpiece of 72 pages filled with original illustrations. The sudden taking off of Dr. Villagrán seems to have been responsible for a dearth of information concerning the circumstances of his death and other biographical details, but it appears that as a Government military surgeon he had done much work in the various provinces in the direction of the extirpation of the pernicious fevers. On September 14, 1918, he had reported officially the existence of yellow fever in Retalhuleu. There was at first but a single victim who had been attacked in the preceding spring at Coatepeque. By July the affection was epidemic in both localities. When word was received that the epidemic had appeared in Puerto de San José and that the resident physician at that point was incapacitated, Dr. Villagrán at once repaired to the town where he met his fatal illness.

Saint-Beuve, Physician.—It seems to be known to but few people that the great French critic of matters literary was once a physician, and Professor Sabrazes in the *Gazette hebdomadaire des scienees médicales* (October 26, 1919, xl, 29) reminds the reader of this coincidence. He had always wished to be a poet but his mother insisted that he study medicine, for he was suited both by nature and inclination for that career. However, he found medicine to suffer from many drawbacks. At that period it was still in the theoretical and empirical stage and held out no certainty of prosperity. Saint-Beuve went as far as the position of interne in the Hôpital Saint-Louis and while there took up journalism as a "side line." On the editorial staff of the newly founded *Globe* he began his career as a critic by some brilliant reviews of books. However, he did not formally abandon medicine until after his first book was published. His admirers are now honoring the fiftieth anniversary of his death, and his first biography appeared in 1874. His earliest criticisms date from about 1843. His first great work was an account of French poetry in the XVI century.

Medical Statistics in Spain.—The city of Madrid consumes daily 140,000 eggs, which means one-quarter of an egg apiece for each Madrilene inhabitant. This may be taken as a measure of the low protein ration now current. The movement to import refrigerated beef seems to be opposed. There is also a great scarcity of flour—in fact the statement is made that there is no flour in the city. Statistics of births, deaths, and marriages show that in all the Spanish capital cities there is a tendency of the deaths to rank the births.—*El Siglo Medico.*

THE TEACHING FUNCTION OF THE HOSPITAL,

WITH ESPECIAL REFERENCE TO GYNECOLOGY.*

BY GEORGE GRAY WARD, JR., M.D.,

NEW YORK.

CHIEF SURGEON, WOMAN'S HOSPITAL.

FROM early times, hospitals which are primarily remedial have always shown a tendency toward becoming centers for the dissemination of medical knowledge. This tendency is but logical, as the eager student will naturally seek to acquire learning from the source where the great masters of medicine search for scientific truths. As a result, schools of medicine were evolved, radiating from the hospital as a center. In the present century, hospitals have increased in vast numbers and are located in every community, so that many are in no way affiliated with medical colleges. These latter hospitals are apt to lose sight of one of their most important functions, namely, the educational function.

The chief function of the hospital is, of course, the care and cure of the patient, but next in importance is the teaching function—teaching the profession at large, the staff, interns, students, and nurses.

The recent movement for hospital standardization, which has been inaugurated by the American College of Surgeons, provides that these institutions shall be investigated to see if they measure up to the standards which will soon be demanded of them by the public at large as well as the medical profession. These standards should require that the staff of the hospital shall recognize as a duty their obligation as teachers, in order that their institution may fulfill an imporant function of extending medical knowledge with resultant benefit to the community. Every hospital, whether connected with a medical school or not, has this duty to perform.

Clinical research can only be done in a hospital. Every hospital is a mine containing hidden treasures of scientific facts awaiting to be dislodged from obscurity by the patient seeker after truth. The obligation to humanity is obvious, and therefore this duty of contributing to knowledge by scientific research is one that cannot be neglected by the staff of a hospital without failure to fulfill properly its educational function.

*Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Seventieth Annual Session of the American Medical Association, Atlantic City, June, 1919.

It is, of course, a great advantage to a hospital if it is so fortunate as to have a college connection. College influence has made great strides of late, and the knowledge that the best interests of patients in the hospitals are promoted by teaching is becoming rapidly appreciated by the laity, so that affiliation with a college is now sought by trustees and considered a valuable asset to their institution. These fortunate hospitals which, owing to their being utilized for clinical instruction of undergraduate students, must perforce fulfil their teaching function in part, at least, are necessarily few in number; but the great majority of the hospitals of the country which have no such connection have nevertheless their obligation to fulfil properly their teaching function. How many of them are doing it as it should be done? How many of them are taking advantage of their opportunities? The economic waste of the vast amount of clinical material which is at hand, and is now not made use of by the hospitals of the country is enormous, and is lost as material for imparting valuable instruction to the profession, which means, of course, the loss of untold benefit to the community. It is our duty as a profession and as citizens to point out to these institutions their neglect of this important matter and to demand of them that they take advantage of their opportunities in order that they may be made to serve mankind to the utmost. Therefore, all hospitals should be teaching hospitals, and trustees should be educated to the importance of this educational function so that they will demand this work of their appointees as an essential part of their duties.

It is very true that some men lack the instinct to teach; therefore, it is the duty of trustees to appoint men who can and will teach. Teaching is a great stimulus to do better work, and its rewards are proportionate to the effort expended, and the standard of work in the hospital which gives public clinics will inevitably be raised.

The recent supremacy of Germany in the world of medicine was undoubtedly largely due to the fact that all her hospitals were teaching centers. A teaching hospital or clinic will set the standard of medical practice for the profession in its vicinity, as it is an exponent of modern science in its particular field, and its educational value can be hardly exaggerated.

Teaching Interns.—Edward Martin has rightly said that a doctor on graduation from a medical school is only 20 per cent. efficient as a practitioner of medicine, and that service as an intern under proper conditions may provide nearly 80 per cent. of the training of a doctor. The importance of

providing a service for the intern under proper conditions in order that he may be fitted to practice medicine in the community is therefore self-evident, and the obligation of the hospital cannot be neglected without failing to fulfill this teaching function which belongs to it. It is too frequently the custom to place young men fresh from the medical schools in the hospitals as interns with no supervision from anyone who feels any direct responsibility for their instruction or guidance. Too often they are expected to pick up knowledge themselves as best they can.

The staff should always have this obligation in mind, and in making rounds the intern should be made to feel that his work and responsibilities must be taken seriously; that carelessness and neglect are serious offenses which may cause material damage to the patient. He should be instructed as if still an undergraduate, and his work helpfully supervised. He should be encouraged to make his own diagnoses and to give his reasons therefor. He should be urged to consult the literature bearing on his cases and facilities should be provided in order that he may conveniently do so. Above all, he should be taught how to take a complete and proper history, and the careful execution of this important but often neglected work should be insisted upon. He should clearly understand that what operations he may be allowed to do under supervision are as a reward for efficiency and proportionate to his faithful and conscientious performance of his duties and his adaptability for the work. There is no better way to stimulate his imagination and enthusiasm than by giving him practical research problems to work out from the cases under his observation. By giving personal instruction to the intern we are not only benefiting him but are after all providing for the welfare and proper care of future patients as well as insuring the best service to present patients.

This time and trouble spent in teaching interns is not pure altruism, for much of the success of our own work depends on the intelligent interest and conscientious performance of duty by our assistants on the house staff.

The organization of the intern staff should provide a well balanced service insuring each intern work in every department. The discipline and proper execution of the work of the staff will be greatly facilitated if provision is made for a resident who is the chief in charge of the staff and responsible for their conduct and duties.

In the Woman's Hospital in New York, the house staff has been organized with these ends in view. There is a paid resident gynecologist, who is in control of the entire intern staff and who is held responsible for their discipline and work. He arranges for the daily work in the operating rooms, and provides for leaves of absence and substitution. All cases of serious illness and deaths must be promptly reported to him. He is in charge of all the private patients, and assists the attending staff with these cases. He is directly responsible to the chief surgeon for the proper management of the house staff. The obstetric service is also in the care of a paid resident. The service of the paid residents is indeterminate and may continue as long as their work is satisfactory. They are given larger responsibilities than the intern staff and are encouraged to utilize their opportunities for research work.

The intern staff proper comprises two divisions, each consisting of a house surgeon with a senior and a junior assistant. Their service is for one year, and they serve in each position for four months. Each junior assistant serves two months on the obstetric service, as we believe a man will be better prepared for gynecologic work if he has special obstetric training. The two divisions exchange services every two months so that each intern is given the opportunity to work with all the attending staff.

The pathologic work is in the care of two full-time pathologists, with two technicians, who do the routine work of the hospital; but the junior assistant who is not on the obstetric service is expected to do whatever laboratory work may be required by the service after hours, on Sundays, holidays, and in emergencies. The senior assistants take the histories of all cases and make and record the physical examinations. Blood pressures, complete blood counts, cervical and urethral smears, and Wassermanns, in addition to the ordinary urine examinations, are required as a routine in all cases on admission. The histories of all cases admitted not later than 4 P. M. are sent to the record room to be typewritten and are expected to be in the ward in time for the next morning rounds when made by the attending surgeon. The house surgeons act as first assistants at operations and are responsible for the care and conduct of their cases.

This arrangement of the service of the house staff is made to suit the requirements of a special institution such as the Woman's Hospital, which has about 250 beds, three-fourths of which are gynecologic and the remainder obstetric. The interns chosen are preferably men who have already had a general hospital service.

Teaching Nurses.—The instruction of the nurses in a special hospital is a matter that concerns the surgical staff as well as the department of nursing. The nurses come to the Woman's Hospital for a six months' special course. They must have been previously graduated from a school requiring two years' general training. Consequently, in the short period of this postgraduate instruction, it is essential that they be provided with a carefully balanced curriculum which includes a course of lectures planned to cover all the phases of gynecologic and obstetric nursing. Usually lectures given to nurses by members of the attending staff are merely perfunctory. They are frequently carelessly, or not at all, prepared and are often postponed or skipped to suit the convenience of the lecturer. In the Woman's Hospital these lectures are given by the junior attending staff, each member of which is required to give two lectures on assigned subjects each six months on regularly scheduled dates. The need and advantages of having a full-time instructor whose duties require not only teaching and demonstrations, but also a thorough system of inspection of the daily work of the nurses, is of paramount importance and well repays the expense involved by the added efficiency of the nursing which it insures.

One of the most difficult problems of the nursing department of a hospital with a large attending

staff is the proper carrying out of the numerous and varied preoperative and postoperative standing orders. The members of the attending staff, including the assistants, all have their own ideas and methods which they wish used on their respective patients. These standing orders, which are kept on file in the wards, usually are compiled without any thought as to whether they conflict with the meal hours or other essential scheduled routine ward work. Their multiplicity and variety are so confusing as greatly to increase the chance of error, and with the constant rotation of pupil nurses can never be satisfactorily enforced. The ideal plan is to have but *one* set of standardized orders, which are as simple as is consistent with common sense, and which are adjusted to the time schedule of the ward routine. They should be published in such form as to be readily available to nurses, interns or students. One set of standing orders means a saving of time and energy for the nurses and interns, and reduces the chance of error to a minimum, with resulting benefit to the patient and economy to the hospital. They also greatly facilitate the training and teaching of those who may work in the hospital. We have compiled and put in practice in the gynecologic wards of the Woman's Hospital such a set of standardized orders, and after a thorough trial they have proved most satisfactory. Simplicity and clearness were the objects aimed at in their compilation, and the judgment of the head nurses in charge of the wards was the guide as to their practicability, in the endeavor to make them as "fool proof" as possible.

Standardized Orders for Ward Patients and Recovery Room Patients.

Woman's Hospital in the State of New York, Revised, February, 1919.

STANDING ORDERS FOR THE PREPARATION AND AFTER CARE OF OPERATIVE CASES.

The following orders will apply to all patients except Emergency Cases, Complete Lacerations of Sphincter Ani, Vesico-vaginal Fistulæ and Rectal cases, for which special orders will be given by the Attending Surgeon or House Staff.

PREOPERATIVE CARE.

Patients will receive a full tub bath on admission except emergency or very sick cases.

A specimen of urine must be obtained from each patient as soon as possible after admission and sent to the laboratory not later than 4 P. M. If it is not possible to obtain a specimen before this time, the night nurse will send the morning urine to the laboratory the following day.

Castor oil (1 oz.) will be given 48 hours before operation if the case is in the Hospital.

Cases admitted, or ordered to be prepared less than 48 hours before operation, do not get cathartics.

Light meals are to be given on the day preceding operation.

Preparation for operation is to be made on the afternoon of the day preceding the operation, not later than 6 P. M.

All cases will receive both the abdominal and the vaginal preparation.

All cases are to remain in bed after preparation for operation.

PREPARATION ON THE DAY PRECEDING OPERATION.

1. *Shave.*—The entire abdomen and the external genitals are to be shaved commencing at the ensiform and continuing over the pubes and vulva to the coccyx.
2. Tub bath, temperature 100° F.
3. *One* soap suds enema given with a high rectal tube.
4. Wash the abdomen and external genitals with gauze and Tr. Green Soap and warm water, commencing at the ensiform and continuing down over the vulva.
5. Wash the abdomen first with ether and then alcohol, using sterile gauze.
6. Cover the abdomen with sterile gauze.
7. Give a three (3) quart vaginal douche of 1:5,000 Potassium Permanganate Solution, temperature of 110° F.

(Note—The douche may be omitted on order for cases in which there is to be no pelvic surgery.)

8. Cover the vulva with a sterile pad and fasten it to a T binder.

PREPARATION ON THE DAY OF OPERATION.

Not less than two hours and not more than four hours before sending the patient to the Operating Room, paint the abdomen with 3½ per cent. Tr. Iodine and cover with fresh sterile gauze; give the patient a three (3) quart vaginal douche of 1:5,000 Potassium Permanganate Solution, temperature 110° F. and cover vulva with sterile pad fastened to T binder.

Cases to be operated on in the afternoon are to receive on the morning of the same day:

One Soap Suds enema given with a high rectal tube, at least six (6) hours before the operation.

On the day of operation cases do not receive nourishment or liquids within 3 hours of going to the Operating Room. Tea, coffee or broth may be given before this period.

Morphine grs. 1/6 and Atropine grs. 1/150 are to be given per hypo. half an hour before the patient goes to the Operating Room.

(Note—This order may be omitted for cause by direction of the Attending Surgeon.)

POSTOPERATIVE CARE.

Days are to be counted at the completion of each 24 hours.

Temperature, pulse and respiration are to be taken every four (4) hours until the temperature remains normal for 48 hours, after which they are to be taken B.I.D.

Temperatures are to be taken by rectum for the first three (3) days and indicated on the chart by an X; after this time temperatures are to be taken by mouth and recorded in the usual way. Rectal and "Drip" cases to have mouth temperature only.

A specimen of urine must be sent to the laboratory the morning following the operation.

Pain.—Hypodermic of Morphine gr ¼ P.R.N for pain and repeat Q.S. P.R.N. for 48 hours.

Catheterization—Do not catheterize when Curetting Cervix Operations only have been done, unless compulsory.

Catheterize every 8 hours or sooner for cause, until the patient can void. In extensive Cystocele operations (also Mayo and Watkins Interposition Operations) catheterize every 6 hours for 3 days, or sooner for cause.

Dip the point of the catheter in 25 per cent. Argyrol in all cases before introducing it into the urethra.

After catheterization or micturition the external genitals are to be freely flushed with a warm solution of Potassium Permanganate Solution 1:5,000 by *Piteher Douche.*

Thirst.—Nothing is to be given by mouth for 24 hours after operation but sips of *hot* water; then cool faucet water in small amounts if desired. (No ice or ice-water is to be allowed.) After 24 hours, if not nauseated, the patient may have lemon albumin water.

Diet.—After 36 hours the patient may have weak tea or coffee with sugar (*no milk*), lemon albumin water, broth or fermilac in small quantities repeating every 3 hours if desired.

After the bowels move, liquid diet, milk, broths, etc., are to be given every 3 hours until soft and regular diet are ordered by the Attending Surgeon or House Staff.

ABDOMINAL OPERATIONS ALONE OR COMBINED WITH VAGINAL OPERATIONS.

Bowels.—The rectal tube may be left in situ for gas any time after the operation.

On the morning of the *third* day (or at the comple-

tion of 48 hours after operation, if the patient is uncomfortable from gas pains) the patient is to be given the following enema with a high rectal tube:

Sat. Sol. of Epsom Salts.....	2 oz.
Glycerine	2 oz.
Turpentine	½ oz.
Soap Suds	1 qt.

On the morning of the *fourth* day the patient is to be given 1 oz. of Castor Oil followed by a Soap Suds enema 4 hours later if necessary. The bowels are to be moved each day thereafter by cathartic or enema on order.

Pitcher Douche.—The external genitals and anus are to be cleansed by the *Pitcher Douche* of a warm solution of 1:5,000 Potassium Permanganate after each micturition or defecation. No manual cleansing is to be permitted.

VAGINAL OPERATIONS ALONE.

Bowels.—On the morning of the *third* day the patient is to be given a Soap Suds enema.

On the morning of the *fourth* day the patient is to be given 1 oz. of Castor Oil followed by a Soap Suds enema four (4) hours later if necessary.

Pitcher Douche.—The external genitals and anus are to be cleansed by the *Pitcher Douche* of a warm solution of 1:5,000 Potassium Permanganate after each micturition or defecation. No manual cleansing is to be permitted.

Douches.—After the *seventh* day a vaginal douche of 1.5,000 Potassium Permanganate Solution, temperature 110 F. is to be given daily with a soft rubber catheter.

COMBINED ABDOMINAL AND VAGINAL OPERATIONS.

After the *seventh day* a vaginal douche of 1:5,000 Potassium Permanganate Solution, temperature 110° F. is to be given daily with a soft rubber catheter.

DRAINAGE.

All drains with their location and the date they are to be removed must be charted in red ink on the Order Slip of the Case History. The removal of the drains will be by special order of the Attending Surgeon or House Staff.

COMPLICATIONS.

All cases developing complications will receive special orders from the Attending Surgeon or House Staff.

OUT OF BED.

All cases will be allowed out of bed only on special order from Attending Surgeon or House Staff.

The First Day Out of Bed the patients are allowed to sit up for one hour.

The Second Day Out of Bed the patients are allowed to sit up one hour in the morning and one hour in the afternoon.

Thereafter the length of time out of bed is to be gradually increased, but no patient is to remain up longer than four hours in the morning and four hours in the afternoon until ready for discharge.

STANDING ORDERS FOR THE RECOVERY WARD.
POST-OPERATIVE CARE.

The following orders will apply to all patients except Emergency Cases, Complete Lacerations of the Sphincter Ani, Vesico-vaginal Fistulæ and Rectal cases, for which special orders will be given by the Attending Surgeon or House Staff.

Beds.—The beds in Recovery Ward are to be prepared for the reception of patients from the Operating Room according to the Woman's Hospital rule.

The *Bed* must be properly warmed for the reception of the patient by hot water bottles, but all hot water bottles are to be removed when the patient is placed in the bed, unless ordered to be retained by a written order from the Attending Surgeon or House Staff.

When the cases are in shock or collapse heat is to be maintained by hot blankets, which are to be renewed as needed by blankets taken from the blanket warmer in the small Operating Room.

Hot water bottles are to be filled from a pitcher and the temperature of the water must not exceed 120° F.

Hot water bottles are never to be applied to the patient except on a written order from the Attending Surgeon or House Staff, and in every case they must be separated from the patient by a blanket.

As soon as the patient is placed in bed all wet clothing is to be removed.

The abdominal binder is to be adjusted and securely pinned.

All pins are to be removed from the sleeves.

A Draw Sheet is to be placed as a restraining sheet across the abdomen, but not so as to cause pressure or restrict breathing.

The Head is to be turned on one side, with a towel and basin under the chin.

The Pulse and Respiration are to be taken every 15 minutes until the patient is conscious, or as long as she is in a condition of danger from shock or collapse, after which they are to be taken every hour until patient is removed from Recovery Room.

Hemorrhage.—All patients are to be watched for hemorrhage from the incision and from the vagina, an inspection being made every half hour.

Temperature.—All temperatures will be taken every 4 hours by rectum and indicated on the chart by an X (except in cases of Complete Laceration of the Perineum and Rectal and Drip cases when mouth temperature will be taken).

Pain.—A hypodermic of Morphine gr ¼ P.R.N. for pain and repeat Q.S. P.R.N.

Catheterization.—Do not catheterize when Curetting and Cervix Operations only have been done, unless compulsory. Catheterize every 8 hours or sooner for cause, unless the patient can void.

In extensive Cystocele Operations (also in Mayo and Watkins Interposition operations), catheterize every 6 hours or sooner for cause.

Dip the point of the catheter in 25 per cent. Argyrol in all cases before introducing it into the urethra.

After catheterization or micturition or defecation, the external genitals are to be freely flushed with a warm Solution of Potassium Permanganate 1:5,000 by *Pitcher Douche.*

No manual cleansing is allowed.

In vaginal operations a fresh sterile vulva pad is to be applied.

Thirst.—Nothing is to be given by mouth for 24 hours after operation but sips of *hot* water (*No ice or Ice Water is to be allowed*).

Drains.—All drains with their location and the date they are to be removed must be charted in red ink on the order slip of the Case History.

Urine.—A specimen of urine must be sent to the laboratory the morning following the operation.

Complications.—Any unusual condition of the patient is to be reported at once to the House Surgeon in charge of the case and to the Directress of Nurses.

All cases developing complications will receive special orders from the Attending Surgeon or House Staff.

Teaching the Attending Staff.—The educational possibilities of a hospital service to the attending staff are immeasurable, and no one should be retained who fails to appreciate and take advantage of the opportunities presented. The outpatient department offers one of the best oportunities for clinical instruction to the younger men who are ambitious to attain staff appointments, but as a rule they do not avail themselves of this privilege. The work done is frequently superficial and perfunctory, and the diagnoses carelessly and hurriedly made. Clinical research is rarely attempted. This waste of opportunity is largely due to the fact that as a rule there is no supervision of the work in this department, the men being left to their own sweet wills and to the feeling that promotion is only to be attained by "pull" or favor. If it is distinctly understood that the positions of chief of clinic will lead directly to the hospital staff appointments and that the work done is under supervision with that object in view, these outpatient positions will be sought for and will attract the best type of men. If they are expected to teach undergradu-

ate students and have a definite schedule of demonstrations which they are required to give at specified times, they will be stimulated to put forth their best efforts to the mutual benefit of all concerned.

We have attempted to accomplish this object in the outpatient department of the Woman's Hospital by such supervision and teaching. The men have been given to understand that the opportunity to obtain promotion to the attending staff is open to them in accordance with their work, but that their work must give evidence of some study or clinical research. The hospital wards, the laboratories, and the records are freely available for this purpose.

They are expected to take part in the weekly clinical conferences and are encouraged to follow their referred cases to the operating room and during convalescence. During the summer months, when the junior attending staff act as the attending surgeons, they automatically come into the hospital as acting junior attendings, and thus have an opportunity to develop and show their worth in the operating rooms and in the wards.

A valuable aid in observing and judging their ability is the "reference sheet" which has been established as the connecting link between the outpatient department and the wards. Each patient who is referred from this department is accompanied with a form which must be filled out and signed by the clinic chief. This contains all the data relating to the patient while in the outpatient department, including the physical findings and tentative diagnosis as made by the man referring the case. He thus places his opinions on record where they are certain to be observed by the attending staff. The third year students of the Cornell University Medical College receive part of their practical training in the outpatient department of the hospital, and each chief of clinic acts as the instructor and is required to demonstrate the various methods of diagnosis and treatment and to show as many conditions and diseases as the material may afford in accordance with a definite schedule of instruction.

The entire hospital staff, seniors and juniors, should be engaged on problems of clinical research as part of their daily duty in addition to their routine work. A necessary foundation for clinical research in a surgical hospital is the thorough, careful, and complete preoperative study of the patient; otherwise any deductions that may be made are of doubtful value. In order to accomplish this it is essential that the patients remain in the hospital a sufficient time before operation to permit of the necessary examination and laboratory tests to be made. This is not wasteful of hospital beds, as the time spent will be more than saved in the end by the avoidance of errors due to hasty and incomplete diagnoses, and by the great gain to the hospital in reputation and abundance of patients as a result of the superior quality of the work done. Trustees should realize that the usefulness of an institution should be estimated by the quality of the work done and not by the quantity, for as someone has said, "If the quality be poor, the larger it is, the worse for the public and the profession."

In the Woman's Hospital the average stay of a patient before operation is three or four days, in order that she may be properly studied. This allows of the necessary laboratory tests being made and complete history being taken, with time for the attending surgeon to check it up, and for the obtaining of consultations when needed. We have established a completely equipped gastroenterologic department, which is a very valuable and necessary adjunct to a gynecologic hospital. This department is used solely for gynecologic cases having associated gastroenterologic conditions, and not for gastroenterology *per se*, as the work of the hospital is gynecologic and obstetric only. An appropriate form called a "consultation sheet" is provided in the case history for the recording of any consultations that may be made, which must be signed by the consultant.

Valuable information is made readily available for study by the employment of a form in the case history which we call the "wound sheet." On this sheet is recorded the complete record of the healing of the wounds of operation. Provision is made for abdominal and vaginal wounds, the site, character, nature of the operation, nonabsorbable sutures, drainage, and whether the case was clean or a contaminated one, which are charted at the time of operation. Each time the wound is inspected or dressed it must be recorded and signed by the surgeon and the character of the dressing stated. If the wound is purulent, a culture must be taken and the nature of the organism given, in accordance with the laboratory report. On the discharge of the patient the condition of the wound must be recorded. When the case histories reach the department of records, the clerks abstract the data from these wound sheets on a card index, where each surgeon's record of the healing of his operative wounds is made readily available and is open to all concerned.

All members of the hospital staff, both seniors and juniors, in all departments, are expected to make some study as a contribution to the literature during the year. If any particular type of case is desired by any of the staff for the purpose of clinical research, all that is necessary is for him to notify the chief surgeon of his desire and object, and such material will be assigned to him in quantity sufficient for his purpose, as far as the service will allow; but he must present his results for publication in the annual surgical report of the hospital, which is made up of the scientific contributions of the staff. To facilitate this important work we have established a library in the hospital with the latest editions of the standard textbooks and the periodicals on gynecology and obstetrics, through the generosity of the board of governors, and they have also provided the services of a medical artist who is at the disposal of the staff at stated periods.

Periodic staff conferences are essential to bring the men together in order that they may get in touch, learn one another's point of view, and exchange ideas. Opportunity is thus presented for the discussion of problems, checking up of the results, and investigating errors, all of which is bound to result in vast benefits to the hospital, the physicians, and primarily to the patients. The educational value of such conferences is unquesfionable and is a stimulus to the work of the entire staff. At

the Woman's Hospital, staff conferences are held each week throughout nine months of the year. They last about one hour and the usual order of procedure is as follows:

Presentation by the pathologists of pathologic material of interest which have been obtained during the week. The gross and microscopic specimens are demonstrated and brief talks on the pathology are given.

The casualties of the service are next called for. Each attending surgeon must report any deaths, infections, or complications occurring during the week, and an endeavor is made to locate the cause. The details, as shown by the case histories, and the testimony of those concerned are carefully analyzed in order that it may be determined as far as possible whether the fault lay with the physician, the patient, the disease, or the hospital organization or equipment.

A report on the analysis of the follow-up clinic of one of the attending surgeons is next made. Each of the four attending surgeons has such a clinic once a week which they must attend in person, and once in four weeks they are required to make an analysis of the results of the cases they have seen since their previous report. This analysis must show the total number of cases seen in the clinic and the number which have been previously reported. The remainder which are to be reported are classified according to the results as successful, partially successful, and failures. The acid test for the determination of the result is whether the patient has been cured of the symptoms for which she sought relief, and not whether the operative result is satisfactory to the surgeon. The successful cases are disregarded, while each partially successful case and failure must be analyzed in detail and the reasons given for the classification. A free discussion is encouraged in order that the operating surgeon may have every opportunity to defend his position. Cases that have been previously reported as successful which may later become partially successful or failures must be subsequently reported with their revised classification.

Next a report of some case of special interest is made by one of the attending surgeons in turn; thus an opportunity is given to present case histories or to show the patients which have had successful results. Frequently a case presenting difficulties in diagnosis or treatment is shown and the advice of the conference is sought.

Once a month the junior attending surgeons are required in turn to give a brief summary of the recent gynecologic and obstetric literature, or to give a report on any hospital or operative clinic they may visit. A stenographer is present during the conference who makes a complete typewritten report of the proceedings, which are kept on file in the chief surgeon's office for further study.

Teaching Students.—The teaching of undergraduate students of the Cornell University Medical College in the Woman's Hospital is given during their third and fourth years.

The third-year students, after having completed a course of didactic lectures and demonstrations in gynecology, receive practical instruction in diagnosis and treatment in the outpatient department in sections of four students.

The fourth-year students, in sections, spend half time (9 to 1 P.M.) for two weeks, and full time (9 A.M. to 5 P.M.) for two weeks in the hospital. They practically receive intensive daily instruction in the subject as clinical clerks for one month, which is the most efficient and ideal method. Their course includes work in the wards, where they are taught history taking, and they make daily rounds with the attending surgeon, during which they have an opportunity to study the cases before and after operation. They witness the operations and see the specimens demonstrated in the laboratory, so that they are enabled to follow the cases from admission to discharge during their stay in the hospital. They are given opportunity to examine suitable cases under anesthesia and to see the work in the cystoscopic, gastroenterologic, and outpatient departments. This work in the third and fourth year is required of all students.

During the last term of the senior year, the students spend their time entirely in elective studies. We give an elective course in gynecology at the Woman's Hospital which provides for a group of

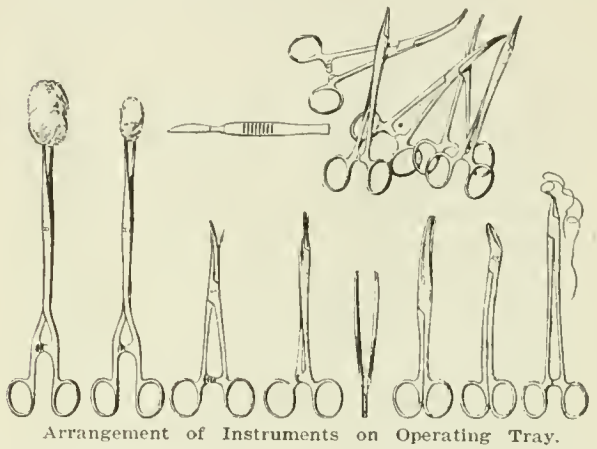
four students working as clinical clerks from 9 A.M. to 5 P.M. daily for one month. The work is divided into two schedules. Each section of two students completes a schedule in two weeks, when the sections exchange schedules. A new group starts each month. They are required to act as second assistant at operations, and a research problem is given each one at the commencement of the work, which he is required to present at the termination of the course in the form of a thesis. These problems are worked up during the time assigned to study, and they are taught how to utilize the record room for the abstraction of facts from the hospital histories.

During the term just finished, the following problems were given to the students taking the elective courses: "A Study of the Relation of Appendicitis to Right-sided Adnexal Disease," "A Study of Postoperative Catheterization in Relation to Vaginal Operations," and "A Study of Postoperative Vomiting in Relation to Abdominal Operations." Each student was required to present an independent thesis, although they were allowed to work in groups of two on one subject. Several of these theses were of exceptional merit and will be published in the surgical report of the hospital.

From the accompanying schedule it will be seen that, in a month's course on intensive all-day training under supervision in every department of such a special hospital, the student has exceptional opportunities to obtain practical knowledge.

Teaching the Profession.—It is unfortunately true that, in New York at least, many of our best clinicians, surgical as well as medical, fail to realize their duty to the profession in giving teaching clinics. Until a few years ago it was not possible for the stranger or a resident in New York to obtain information as to when he might be able to witness surgical or medical clinics without unusual difficulty. Today this has been remedied somewhat by the establishment of a bureau of information at the Academy of Medicine by a number of the profession who formed a society to provide the necessary funds. A daily bulletin of operative clinics is now issued and mailed for a small fee. This bulletin consists almost entirely of surgical clinics, as it is nearly impossible to get the medical men to do their part, although there is a constant demand or inquiry for medical clinics. Many of the surgeons make little or no attempt to teach, considering that mere admission to witness the operations is all that is required. The failure to present properly the history of the case with the results of the various diagnostic tests, the reasons for making the diagnosis, and the treatment to be employed, is far too frequent. A physician referring a patient to the hospital should have the courtesy of an invitation to the operation, and the patient should be referred back to him with a copy of the diagnosis. By so doing the hospital will be fulfilling one of its functions of educating the profession. A lack of courtesy is not uncommon. A professional brother is certainly entitled to a courteous reception that makes him feel that he is welcome, for he is paying the surgeon a real compliment by spending his time to witness his work.

Teaching Methods.—Simplification of procedure as accomplished by standardization of methods greatly facilitates the imparting of knowledge to the student in such a form as to avoid confusion and complexity, and favors its retention. Consequently we have standardized the technic of the usual gynecologic operations, and we endeavor to carry out each step of the procedures in a uniform way. Thus the interns and nurses rapidly learn the technic of each operation, and their value as assistants is proportionately increased. A description of the technic of each standardized operation is kept on file in the record room, so that in the dictation of the operation to the stenographer much time and work are saved, as it is only necessary to give the nature of the operative procedure. When the surgeon has no order or system in his method of operating, the patient's interests are jeopardized. We have had illustrations made of each step of these standardized operations, and use the stereomotograph to show the lantern slides of these while executing them, to the great satisfaction of the observers, who are thus enabled to follow each step accurately.



Arrangement of Instruments on Operating Tray.

We have standardized the arrangement of the instruments on the operating tray, as shown in the accompanying illustration. These instruments, which are those in most constant use, must be kept in their proper location by the suture nurse. When the operator takes one from the tray, she must substitute its duplicate at once, so that the surgeon always finds the same instrument in the same place, and confusion and waste of time are avoided. The upper part of the tray is used for the discard. The suture nurse watches the tray and not the operation, so that her duties are greatly simplified. It is therefore only necessary to ask for some special instrument. Lists of those required for each type of operation have been made so that there will be an avoidance of wear and tear on a great number of unneeded ones which would have been unnecessarily prepared.

Among our most important duties as teachers is our obligation to develop competent successors. This implies that we should give every opportunity to the younger men of the staff to develop and fit themselves for the senior positions. Many a man remains a good assistant all his life, because he has not been given the chance to do independent work owing to the selfishness of his chief.

The development of a medical center is a matter which is vitally dependent on the hospitals of a community fulfilling their teaching function in the broadest sense. If they do this, they are certain

to attract those who are eager for knowledge from far and near.

The trustees of our hospitals should realize that the influences and spirit of a hospital should make not only for high ideas of its remedial function, but also for its teaching function, and that unless the proper spirit prevails within its walls, it will fail in the fulfillment of its full duty to the community. Holt has well said: "The spirit of an institution is something different from its aims. It is the resultant of the attitude of mind, the breadth of outlook, and the personality of the three persons who determine the hospital's policy: the dominating spirit in the board of trustees, the superintendent, and the physician in chief."

71 West 50th Street.

THE INTERNAL SECRETIONS.*

By E. D. FRIEDMAN, M.D.,

NEW YORK.

ADJUNCT ASSISTANT VISITING PHYSICIAN TO THE NEUROLOGIC SERVICE, BELLEVUE HOSPITAL; INSTRUCTOR IN NEUROPATHOLOGY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

Claude Bernard first used the term "internal secretions," applying it to the glycogen and urea formed in the liver and given off to the blood stream. But our clinical knowledge of these important organs dates back to Addison (1855), who first called the attention of the profession to the importance of the lesion in the adrenals in the disease which he described. Gull, Ord, and Charcot (1873) described myxedema. Kocher (1882) and Reverdin (1883) proved that this was due to the absence of the functional activity of the thyroid. The place of the thyroid in Basedow's disease was further emphasized through the operative treatment of hyperthyroidism by Rehn and others. In 1886, Moebius first spoke of hyperthyroidism as the cause of Basedow's disease, and in 1889, Brown-Séquard spoke of the effect of the injection of testicular extracts on distant organs. Mehring and Minkowski proved the pancreas important in the pathogenesis of diabetes mellitus. Later Schulze, Opie, and Weichselbaum emphasized the importance of the lesion in the islands of Langerhans in this disease. Blum discovered the glycosuric effect of suprarenal extract. "Sugar puncture" is thought to produce glycosuria through the discharge of adrenalin into the blood-neurogenic type of diabetes. The chromaffin system was described by Wiesel and is said to be hyperplastic in cardiorenal disease and hypoplastic in status thymo-lymphaticus.

The relation of the parathyroids to tetany was suggested by Gley, Vassale, and Generali, and emphasized by Jeandelize, Pineles, Erdheim, Chvostek, and MacCallum. Pierre Marie associated acromegaly with disease of the hypophysis. Froehlich (1901) and Frankl-Hochwart soon afterward described the syndrome of dystrophy adiposo-genitalis. The pathological study of the hypophysis was carried on specially by Benda and Erdheim. Experimental work on this organ was done in this country by Cushing, and in Italy by Ascoli and Legnani.

*Read before the Clinical Society of the People's Hospital.

Eunuchoidism was accurately described by Tandler and Grosz. The pineal was studied by Frankl-Hochwart and Marburg. Finally, Claude and Gougerot speak of a pluriglandular syndrome, in which all these glands are involved.

Murray was the first to advocate thyroid gland substances for cachexia thyreopriva or cretinism. In our own time organotherapy is keeping pace with the unraveling of the physiologic activity of the glands of internal secretion. It seems a most rational form of therapy to replace a missing principle by feeding the organ which produces this element. Physiologic chemistry has helped in this field and methodic search has been fruitful. In this way Schafer discovered the significance of adrenalin, and the effects of pituitrin. The more advanced our knowledge in this field will be, the greater will be the number of therapeutic indications and possibilities. A number of acute and chronic conditions are already subject to organotherapy.

Definition and Mode of Action.—A gland is said to have an internal secretion when it gives off its secretion to the blood stream. These principles have been termed autacoids or chemical messengers. Only few of these have had their chemical composition determined (alphaiodine, adrenalin, tethelin). In most cases the effects can only be studied by means of gland extracts which are chiefly made up of proteoses, peptones, and peptides. Not all are true glands; for example, the medulla of the adrenals, and the posterior lobe of the pituitary have no gland structure; and when they are, it is not always the parenchyma which furnishes the secretion, as in the case of the interstitial cells of the testis and ovary. Definite proof of the presence of these substances in the blood has been found only in few instances. Noel Paton says of them: "A certain minimum amount of each must be present if metabolism is to continue in its normal course." The active principles are not rendered inert by boiling. Chemically, they seem to be simpler than enzymes. Some act instantly, for example, adrenalin and pituitrin; others act more slowly and are termed morphogenetic (Gley). The extract of the glands may keep indefinitely if sterile, and the dry extract is also potent. Some of these principles seem to be stimulating and are termed hormones, others seem inhibitory and are termed chalones (Schafer).

It has been determined experimentally: First, that the more or less complete removal of these organs causes severe disturbances in the human economy; these are termed "deficiency symptoms." Second, that the reimplantation of the excised organ, even without its normal nerve connection, will remove these deficiency symptoms for some time. Third, that in some instances the same effect can be produced by feeding the organ substance by mouth or by the injection of an extract of the gland. These experimental results demonstrate the significance of these organs to the body and the relative independence of their activity of nervous control. It is also important to note that the administration of organ substance or its extract produces in normal individuals a hyperfunction of the respective organ.

These substances may be administered in several

ways, and the effects vary somewhat with the method of administration. The administration of thyroid extract, for example, by mouth, increases nitrogen elimination, increases the intake of oxygen and the output of CO_2, and reduces the fat of the body. Subcutaneous or intramuscular injection has chiefly local effects because absorption is slow. Intravenous injections of these substances was first practised by Schafer and Oliver in 1894. The intravenous injection of thyroid produces chiefly a fall in blood pressure; the injection of adrenalin produces a rise in blood pressure, increased pulse rate, salivation, erection of hair, dilatation of the pupil, exophthalmos, contraction of the uterus and the vas deferens, and inhibition of the musculature of the gastrointestinal tract and the bladder. Intravenous injection of the extract of the posterior lobe of the pituitary produces contraction of blood vessels, slows the heart, increases the urinary excretion and the milk secretion, and contracts the uterus. The intravenous injection of most of the extracts tends to depress the blood pressure and, if they are unboiled, may cause intravascular clotting.

Pathology and study of disease complexes also have helped to build up our knowledge of these organs. Many constitutional disorders are now thought to be due to hypo- or hyper-function of these structures. The best examples are myxedema as a hypo-function and exophthalmic goitre as a hyper-function of the thyroid; acromegaly as a hyperpituitarism and dystrophy adiposogenitalis (Froehlich) as a hypopituitarism.

There are two theories concerning the activity of these organs. The first ascribes to these glands the function of detoxicating products arising in intermediary metabolism. That such products do exist, we know, when we consider the derivatives of the protein molecule, for example, phenol, cresol, skatol, and others. This theory has few adherents to-day, although some have tried to prove it experimentally. For example, the blood and urine of thyroidectomized and parathyroidectomized animals have been introduced into the blood of normal animals of the same species. Burgi has tested the effect of the blood of such animals on isolated organs. The results, however, were not conclusive. The deficiency symptoms are said to be less intense on protein free diet. Hence the idea of detoxication was advanced. The French, also, are fond of ascribing hyperthyroidism to a latent tuberculous toxemia.

But the hormone theory is the more plausible and the more generally accepted. These autacoids (acos-remedy), chemical messengers, or hormones are physiologic drugs. It was assumed that the activity of the glands of internal secretion was due to a single active principle, but this is probably not so. It is more likely that each gland furnishes a number of hormones. The manifold effects of adrenalin can easily be explained by the relation which it bears to the sympathetic system, but the adrenal cortex also contains a hormone. The active principle of the posterior lobe of the pituitary is also not single. In addition to the principles acting on the uterus and kidney, it produces a substance which plays a considerable role in carbohydrate metabolism, and the anterior lobe of this organ seems to furnish another principle intimately concerned with growth. So it is hard to assume that the same thyroid principle which stimulates growth affects the heart, the bowel, and metabolism, and just as there are many alkaloids in one drug, so each gland of internal secretion probably furnishes a number of principles.

Kohn called attention to the fact that those organs without glandular structure, that is, the medulla of the adrenals and the posterior lobe of the pituitary, seemed to furnish easily demonstrable substances with typical hormone-like action; the secretion of the glandular ones on the contrary, like the thyroid, the cortex of the adrenal, and the anterior lobe of the hypophysis, seems to be more complex and to influence the complicated growth and metabolism phenomena.

As a result of the facts thus far enumerated, we may say that there are three methods of organotherapy; first, we may remove deficiency symptoms through the administration of the organ involved or its extract; or, second, we may make use of the hormone-like action of the organ extract to stimulate function in the gland. Through the work of Falta, Rudinger, Eppinger, and others, we know of the intimate correlation of these organs and so we may, thirdly, make use of one organ extract to stimulate the function of another in the group.

The best example of the interrelationship existing between these organs is seen in the case of the thyroid, adrenal, and pancreas. Thyroid and adrenal medulla are synergists; the pancreas and thyroid, pancreas and adrenal medulla are antagonists. (There are also relationships between the secretory glands and the sex organs.) Falta places the thyroid, posterior lobe of pituitary, chromaffin system, and sex gland parenchyma in the catabolic group; the parathyroids, anterior lobe of the pituitary, suprarenal cortex, pineal, interstitial sex glands, and pancreas in the anabolic group. The treatment of deficiency diseases presupposes that the substance is not destroyed after oral, subcutaneous, or intravenous administration before it has had a chance to produce its effects, and such treatment requires a long period of time. Direct implantation seems the most rational and the most promising.

Thyroid.—The thyroid was first studied by Schiff in 1856. The significance of this organ was cleared up especially by the work of Kocher and Reverdin. The absence of this gland lessens basal metabolism, increases tolerance for carbohydrates, tends toward nitrogen retention, low temperature (due to loss of the thermic regulation of the skin), deposit of mucinous tissue in the subcutis, anemia, dryness and roughness of skin, loss of hair, loss of muscle tone, interference with regeneration of tissue, sexual recession, loss of memory and judgment, and, in the young, mental deterioration (due to atrophy of the cortex). There is also disturbance in bone growth and ossification. The hands and feet are podgy. The fontanelles remain open, the abdomen is large and pendulous, the nose is depressed, and there is absence of the onset of puberty. In the adult we call this condition myxedema or cachexia thyreopriva; in the young it is called cretinism. In the Himalayas there are two kinds of endemic cretinism, the myxedematous type and the nervous type, the latter probably of parathyroid origin.

In the first months of life the cretins get their thyroid hormone from the mother, either through the placenta or the milk, and hence do not develop symptoms until some time after birth. Cachexia strumipriva occurs at varying periods following operation. It is sometimes associated with tetany due to removal of parathyroids also. The longest duration of life is six to seven years. When the gland is not completely out of function we get hypothyroidism. Vincent and Jolly found that in herbivora thyroidectomy produced only diminished resistance to disease. Carnivora usually died as a result of thyroidectomy. This was probably due to the different position of the parathyroids in carnivora, in which they are imbedded in the thyroid; thyroidectomy, therefore, was fatal, due to the removal of parathyroids as well.

Implantation will relieve symptoms, and persistent oral or subcutaneous therapy is also of value; replacement therapy is more effective here than in the case of any other gland of internal secretion. It is stated that in myxedema the patient can be kept in fair health on 60 to 130 mgms. of thyroid extract by mouth given every three or four days (Howell). It is interesting to note that a thyroid carcinoma metastasis will act like thyroid gland itself.

Thyroid extract tends to lower blood pressure, not, however, in diabetes, in which it tends to raise blood pressure. Large doses produce tachycardia, nervousness, flushing of the skin, increased perspiration, increased nitrogen, metabolism, loss of weight, alimentary glycosuria, evidence of stimulation of the cervical sympathetic (dilatation of the pupil, exophthalmos, retraction of the third eyelid in animals), increased respiratory exchange, and tremor—all symptoms of exophthalmic goitre.

Exophthalmic Goiter.—Is Basedow's disease a dysthyroidism or a hyperthyroidism? The operative results seem to favor the hyperthyroid theory. The fact that myxedema is the antithesis of Graves' disease also tends to confirm the hyperthyroid theory. The question whether the cause of Basedow's disease lies really, as Moebius thought, in the thyroid, or in the nerve centers, has not yet been definitely decided, Oppenheim believing it to be a sympathetic neurosis, but most observers believe that Basedow's disease is a hyperthyroidism. It might be mentioned by way of parenthesis that no one has yet experimentally produced exophthalmic goitre. The exophthalmos, too, is hardly ever improved by operative procedures on the thyroid.

Parry (1825), Graves (1835), and Basedow (1840), contributed to our knowledge of this condition. The incidence ratio of females to males is 4.6 to 1. It occurs frequently at puberty and during or after pregnancy. Reid Hunt found that the blood of hyperthyroid cases increases the resistance of mice to acetonitril. Thyroid extract does the same thing.

Between Graves' disease and the normal state there is a whole series of conditions with one or the other of the cardinal symptoms left out. This cannot be sufficiently emphasized, and many cases of so-called neurosis belong in this group, termed by the French *formes frustes.*

Trazewski has advocated the use of phosphate of soda in doses of 5 grams a day, because this salt was said to be antagonistic to the iodine of the thyroid. The Kochers have amplified this view and adopted his therapy. Simple iodides are also injurious in hyperthyroid cases. Reid Hunt and Marine have shown that hormone production is favored by the administration of iodides. There seems to be a definite relationship between the iodide content and the physiologic activity of the gland.

Krehl also has warned against the indiscriminate use of iodides, maintaining that many cases of mild hyperthyroidism are thus brought out. There seems to be 0.3 to 0.9 per mille of iodine in the dry gland substance and the active principle has been called iodothyreoglobulin, iodothyrin, and thyroidin. This contains 9.3 per cent. by weight. The absence of iodine in the thyroid of the new born makes it possible that the protein substance of the gland simply absorbs the iodine and that thyreoglobulin contains the active principle. This is said to stimulate the sympathetic, possibly indirectly by way of the adrenals, which seem to be roused to activity by excessive thyroid secretion in the blood.

Kendall has recently isolated what he calls the active principle of the thyroid (alphaiodine) containing an even larger amount of iodine in its molecule—60 per cent.—and its use has been recommended in cases of heart block.

Before concluding the discussion of the thyroid, we might say a word on the interaction between the thyroid and other glands. The loss of thyroid leads to pituitary overgrowth, due to the abolition of a restraining influence or to vicarious activity. After feeding thyroid the thymus has been found increased in size. The thyroid enlarges at menstruation, at puberty, and during pregnancy. Krause and Kramer found that glycogen disappeared from the liver after thyroid feeding; the latter limits the assimilation of carbohydrate due to increased adrenal activity or inhibition of the pancreas. Parathyroid removal lowers the tolerance for sugar; after thyroid feeding adrenalin produces a stronger glycosuria, while thyroidless animals do not show adrenal glycosuria. Lorand produced pancreatic diabetes and found that after thyroidectomy the sugar disappeared from the urine, demonstrating an antagonism between thyroid and pancreas. The thyroid enhances the action of the adrenals. Ott and Scott found an increase of adrenalin in the blood after the injection of thyroid extract. Krause found dilatation of the pupil of the excised eye of the frog when it was placed in serum from a case of hyperthyroidism. The adrenal content of the blood was increased after the injection of thyroid *pressaft* into animals. This was demonstrated by Frankel by means of the uterus and by Trendelenburg by means of the frog's blood vessels. Thyroid seems to activate the pituitary.

Cyon found that extirpation of the inferior cervical ganglion led to atrophy of the thyroid. This rationalized the operation of excision of the ganglion in exophthalmic goitre. The attempts to treat Basedow's disease with antibodies (antithyroidin Moebius; the serum of thyroidectomized sheep) have been of doubtful value. The administration of thyroid has been advocated for simple degenerative goiter. It was thought that the thyroid extract did the work of the gland and therefore allowed the

latter to atrophy from disuse. Thyroid has been used to influence metabolism; for example, in the treatment of obesity,* it increases metabolism and many obese people lose weight, but if the adiposity is due to anomalies in the other glands, such as the hypophysis or the sex glands, it is not so effective, and obesity cures, due to the increased nitrogen metabolism, are not free from danger.

Thyroid extract has been used to check the hypersecretion of cerebrospinal fluid. It also has a diuretic effect; it can lead to loss of weight due to loss of water from the tissues. Thyroid extract is also used in skin affections, in some forms of mental disturbance, such as dementia praecox, and in syphilis. The signs of tolerance are palpitation, gastrointestinal symptoms, nervous phenomena, excitement, and tremor.

Hypophysis.—The hypophysis is in close relation to the thyroid. It is composed of an anterior lobe which is epithelial in origin and structure, being an invagination of the buccal mucous membrane, an infundibulum which is an outgrowth from the floor of the third ventricle, and a posterior lobe which is nervous.

There is a vestige of the hypophysis in the vault of the pharynx, in the path of the original craniopharyngeal duct. This may account for the mental changes associated with adenoids, so-called aprosexia nasalis. The cells of the anterior part are acidophilic and are increased in pregnancy and acromegaly. The pars intermedia is less vascular and the cells are neutrophilic; the pars nervosa is chiefly made up of neuroglia and is the least vascular. The active principle obtained from pars intermedia and nervosa is pituitrin; it, however, is not a definite chemical body. The secretion passes into the cerebrospinal fluid from the posterior lobe (Cushing and Goetsch). But we must remember that the only secretory cells of the posterior lobe are those of the infundibulum, which are derived from the same source as those of the anterior lobe, and injury to the anterior lobe affects the posterior lobe as well, because the latter receives its raw material from the anterior lobe. The principle obtained from the anterior lobe is called tethelin. This was isolated by Robertson.

The anterior lobe seems to affect growth. Pierre Marie thought that acromegaly was due to a hypofunction of the anterior lobe. Now we know that this leads rather to the Froehlich syndrome, and substitution therapy is therefore of value only in hypofunction. A few cases have been reported benefited.

Howell (1898) demonstrated the direct effect of pituitrin on the vessels. The heart was slowed and blood pressure rose. It is less active than adrenalin, but its action is more prolonged. Reinjection of pituitrin does not raise blood pressure, unless the injections are far apart, thus differing from adrenalin. Pituitrin stimulates the muscles of the stomach, intestine, and uterus. It dilates the pupil. It is not a specific sympathetic stimulant like adrenalin, but it is a direct stimulant to involuntary muscle. It tends to dilate the kidney vessels and increases the secretion of urine; it also directly stimulates the kidney tissue without changing the blood pressure or the renal circulation; this may explain its relationship to diabetes insipidus. It stimulates the secretion of cerebrospinal fluid and causes glycosuria. If injected into a vein it causes the flow of milk, emptying the aveoli by contracting the muscle around them. Placental extract will inhibit this action of pituitrin. (One of the Pyophagus twins was pregnant and both had milk, produced probably by the pituitary hormone of the pregnant one.) When injected into the blood, it causes the disappearance of glycogen from the liver and decreased tolerance for sugar. Given by mouth, its action is slight, due to too slow absorption. Injection of anterior lobe extract produces no definite symptoms.

Evidently there are a number of hormones furnished by the pituitary, one for milk secretion, one affecting the uterus and other involuntary muscles, a diuretic principle, one regulating carbohydrate metabolism, and a morphogenetic principle (anterior lobe).

Paulesco found that removal of the hypophysis, if complete, is fatal. Severing the stalk was also fatal. This was confirmed by Cushing, who found this operation to be fatal in two to five days. Puppis found it fatal in ten to thirty days. The delay in the fatal issue in Puppis' experiments may have been due to the presence of accessory glands. He did not find section of the stalk to be fatal. Section of the stalk interferes with the blood supply to all cells. Incomplete removal of the anterior lobe, according to Cushing, leads to hypopituitarism, infantilism, absence of sex development. Ball found genital atrophy under the same conditions. Complete removal of the anterior lobe seems fatal. Removal of the posterior lobe seems not to be fatal. Biedl, Ascoli, and Legnani confirmed this. Blair Bell produced hypopituitarism by section of the stalk. This interferes with the blood supply to the gland, resulting in insufficiency of secretion. Probably the hypophysis is one organ and the blood stream is the real path for the absorption of the pituitary hormone. (*Quarterly Journal of Physiology*, 1917, ii, 77.)

Apituitarism causes lethargy, refusal of food, poor response of the animal to the voice, slow respiration, slow and feeble pulse, hypotonia of the muscles with twitchings, arching of the back, subnormal temperature, and coma. In later experiments, Cushing did not get uniformly fatal results; nor did Aschner; the result simply was hypopituitarism. The animals, if young, remained small, retained their milk teeth, lanugo hair persisted, the epiphyses remained unankylosed. The thyroid was enlarged, the thymus persisted, the adrenal cortex was thickened, the sex organs remained infantile, and there was a tendency to fat deposition. There was increased tolerance for carbohydrates due to the deficiency of the posterior lobe secretion (extract of posterior lobe causes glycosuria). Such animals may be depancreatized, and yet we get no glycosuria. In adults the chief effect was the deposition of fat; the blood CO_2 was found decreased by Benedict and Holmes. The injury to the posterior lobe seems to cause first polyuria and glycosuria, later polyuria alone. Simonds found tumor of the pars nervosa associated with diabetes insipi-

*In metabolism and growth disturbances, it is advisable to use combined therapy, for example, thyroid and pituitary.

dus. Cushing believes that stimulation of the cervical sympathetic can cause diuresis by way of the posterior lobe of the pituitary. Puncture of the pituitary gives glycosuria, if there is available glycogen in the body, not, however, after section of the cord.

Grafting has been a failure thus far. Feeding the pituitary was found to cause greater laying of eggs in hens (Clark, *Bio. Chem.*, Oct., 1915). Injections of the extract have given conflicting results.

In cases of enlargement of the anterior lobe, we get first hyperpituitarism, later hypopituitarism, and finally apituitarism.

The symptoms are diminution in the visual fields, or bitemporal hemianopsia, and development of the syndrome of acromegaly (described by Pierre Marie, 1886), enlarged extremities, especially the distal parts, massive elongated face, thick lips, large tongue, kyphosis, expressionless faces, mushrooming of the distal phalanx (*x*-ray). In the adult there is no increase in height. In young there may be gigantism.* The sella turcica is enlarged and flattened and the clinoid processes are obscured. There is thickening of the skin, sweating, hypertrichosis, diminished sex activity, occasional glycosuria and polyuria due to irritation of the pars nervosa and intermedia. Removal of an adenoma in the hypophysis frequently relieves the above named symptoms, hence the theory of hyperpituitarism. But no one has yet produced acromegaly by experimental methods, by feeding or by operation.

In pregnancy the pituitary enlarges and the eosinophilic cells increase. Glycosuria is also frequent.

Tumors in the neighborhood of the pituitary produce irritation signs, and therefore glycosuria. When these tumors interfere with blood supply they initiate degenerative changes in the cells of the anterior lobe and lead to the Froehlich syndrome. Destructive tumors produce hypopituitarism due to diminished function of the posterior lobe. This leads to obesity, sex infantilism and increased tolerance for carbohydrates. This syndrome was first described by Bartels, later by Froelich. Madelung in 1904 reported a case which was produced by a bullet in the pituitary.

Hypopituitarism.—If the disease sets in before puberty, the individuals remain small. They are adipose, in females menses are irregular or absent, sex characters are deficient. In the male there is a tendency to femininity—broad pelvis, rounded limbs, small hands and feet, with tapering fingers, and large breasts. There is persistence of the epiphyseal lines in the *x*-ray, smooth, delicate skin, small, thin nails with the absence of crescents at the base, tendency to hibernation, and adiposity. The temperature is subnormal, blood pressure is low, the heart beat is infrequent. There may be a tendency to epilepsy. This syndrome is due to destruction or atrophy of the gland. There may be brain pressure symptoms, imbecility, visual disturbances, etc.

Hypopituitarism in the adult is associated with low temperature, increased tolerance for carbohydrates, adiposity, dryness of the skin, loss of hair, female distribution of the hair in males, pigmentation of the skin (possibly of adrenal origin). The adiposity is due to the deficiency of the posterior lobe secretion; it is never associated with glycosuria, which seems to be the result of increased activity of the posterior lobe.* The anterior lobe seems to furnish a growth hormone and is vital for life. The posterior lobe secretion stimulates plain muscle, the secretory activity of the glands, induces glycogenolysis, and has a regulating influence on the sex organs.

Relation to Other Organs of Internal Secretion.—Duodenal extract seems to stimulate the secretion of the posterior lobe into the cerebrospinal fluid. There seems to be some relation between the pituitary and the glycogenic function of the liver. The removal of the pituitary causes regression of the spleen, atrophy of the thymus, enlargement of the thyroid, and increase in the lipoids of the adrenal cortex. There is an increase in the size of the pituitary and the number of large acidophilic cells in the anterior lobe in castrates. The changes in the pituitary as a result of castration can be avoided by the implantation of the ovary or testis, and here the effect seems to be due rather to the interstitial cells, because the parenchyma undergoes atrophy quickly after implantation. Both menstruation and pregnancy are associated with increase in size of the hypophysis.

Rogowitsch, in 1886, found that the pituitary enlarges after removal of the thyroid, and it enlarges chiefly in its pars anterior and intermedia. This is seen also in myxedema.

Thyroidectomy causes an increase in the hyaline and granular masses of colloid of the pars intermedia; parathyroidectomy does the same. Pituitary colloid contains no iodine, yet the pituitary seems similar to the thyroid in its effects on body growth and the sex organs. Depancreatization leads to glycosuria through interference with the glycogenic function of the liver, the glycogen being rapidly changed to sugar. The injection of adrenalin or swabbing the pancreas with adrenalin produces a similar effect. Injection of pituitrin does the same, hence there seems to be a certain correlation between the pituitary, adrenal, thyroid, and pancreas in their effects on carbohydrate metabolism. The thyroid seems to activate the adrenals and a deficiency of thyroid seems to cause increased secretion of posterior lobe of pituitary. The posterior lobe extract is of more importance in therapy. Oliver and Schafer have called attention to the effects of this substance. The diuretic effect is seldom made use of. Its effect on the heart is still less known. It is used in cases of shock, adynamic ileus, and intestinal atony. It is used most commonly to increase labor pains, especially in the second stage, where it frequently eliminates the necessity for forceps. It is disappointing in postpartum hemorrhage and for the induction of premature labor. Pituitrin has also been used to check hemorrhage, to tone up the bladder, to relieve bronchospasm. It has been recommended for epilepsy. Pituitrin is furnished in ampules; the injections are somewhat painful. For the Froehlich syndrome

*There is a type of gigantism without pituitary enlargement, with defective sex development, similar to the gigantism of those who have been castrated before puberty (thymic in origin).

*Dwarfism is said to be due to a deficiency of the anterior lobe.

whole gland is advised. Anterior lobe extract has been used to stimulate growth. After large doses of pituitrin there is a preliminary fall with subsequent rise in blood pressure, hence the danger of its use in cardiorenal disease and angina pectoris.

Adrenals.—Addison, in 1855, called attention to the fact that languor, debility, hypotonia, both skeletal and visceral, feeble heart action, loss of appetite, gastrointestinal symptoms, pain, emaciation, and pigmentation were due to disease of the adrenals. Some cases have, according to some observers, been improved by the administration of adrenalin. We must note that the cortex of the adrenal is mesodermal in origin, while the medulla forms part of the sympathetic or chromaffin system. We know of the cortex only that it is vital for life. If it is removed, the animal dies with a fall in blood pressure and temperature and marked prostration. There is no replacement therapy possible. The cortex has definite relation to the sex glands and enlarges in castrates. The cortex also enlarges in pregnancy and breeding. This may account for the hypercholesterinemia of pregnancy. It seems to be concerned in the differentiation of the sexual cells. It is rich in lipoids and fats, and may be the source of myelin for nerve fibers. It seems to bear relationship to the cerebral hemispheres. For example, in anencephalics, the cortex of the adrenals is poorly developed. The cortex increases more rapidly than the medulla, and increases with the activity of the sex glands. An abnormal increase in the adrenal cortex is associated with sexual precocity. In hypoplasia of the adrenals there are changes in the cells of Leydig. The lower animals have more adrenal cortex. In fishes the cortex is a separate structure. The adrenal cortex is small where there is deficient sex development.

The medulla is of greater significance. The secretion of the medulla is adrenalin, which occurs in the whole chromaffinic system. (With chromates, sympathetic cells give a brownish yellow stain, hence the name chromaffinic.) The sympathetic ganglia contain two kinds of cells, true nerve cells and the so-called sympathetic cells mentioned above. Langley and Elliott consider adrenalin a stimulus for the thoracolumbar part of the autonomic system, that is, the sympathetic system proper. The general practitioner knows chiefly of the vasoconstrictor effect. It acts on the peripheral nerve ends, hence is of value also in paresis of the vasomotor center with resulting collapse. On intravenous injection there is a rise in blood pressure (this effect is due to action on plain muscle innervated by the sympathetic) and the heart is stimulated directly through the sympathetic fibers; but the action of adrenalin is brief. It is apparently constantly being given off from the medulla of the adrenal to the blood and rapidly rendered inert. Various tests have been used for its detection. Meltzer used frog's pupil (dilatation), Meyer rings of arterial wall (contraction), Cannon and Hoskins intestinal strips (inhibition). The pulmonary and coronary vessels are dilated, hence it is not to be used in pulmonary hemorrhage, but it may be of value in angina.

Brown-Séquard, in 1856, found that double extirpation of the adrenals was fatal. The animals became less lively and developed muscular weakness with low temperature, feeble pulse, low blood pressure, and dyspnea. Bronzing of skin is not seen in animals. Grafting was unsuccessful and suprarenal extract could not save life. Castrates seemed to live longer after extirpation of the adrenals. Biedl found that one-eighth of the adrenal was sufficient for life, and the cortex, he thought, was most vital. Diphtheria and cholera seem to diminish the output of adrenalin. Only the extract of the medulla has potency. This was shown by Oliver and Schafer in 1895. The chromophilic substance was isolated by Frankel, prepared by Von Furth, Abel, and Takamine. Aldrich prepared a crystalline form. Chemically it is orthodioxyphenylethylol methylamine (Stolz and Dakin), and seems to have some relation to tyrosin due to the common oxyphenyl group. It is also similar to melanin.

Intravenous injection frequently produces, in addition to the symptoms named above, slowing of the heart with a cessation of auricular beats due to the effect on the vagus. If the vagi are cut, the rate is increased, the force of the heart is augmented, and the blood pressure rises higher. Its action is brief—a few minutes. The splanchnic area seems to be chiefly affected, the peripheral vessels next, the vessels of the limbs and the trunk less, and the vessels of the brain, heart, and lungs least. The effect is due partly to action on the vessel wall, and is seen even after the nerve supply is cut. But the action of adrenalin is not on muscle fiber alone, because muscles without sympathetic nerve fibers (coronary, pulmonary, and cerebral) are not contracted by adrenalin. Other muscles supplied by the sympathetic are also affected. There is increased contraction of the sphincters (pyloric and ileocecal), of the musculature of the vagina, uterus, and vas. There is inhibition, due to action on inhibitory sympathetic fibers of the musculature of the esophagus, stomach, intestine, bronchi, gall-bladder, urinary bladder, and iris. The eye is protruded. The third eyelid in animals is retracted. The palpebral fissure is widened, and the pupil is dilated. If the superior cervical ganglion is removed, adrenalin instillation into the eye will dilate the pupil on that side. In a depancreatized diabetic, the pupil will dilate on instillation of adrenalin into the eye without the ganglion having been removed. Adrenalin occasionally paralyzes the heart, due to a great increase in peripheral resistance (own case). Traczewski and Burgi demonstrated that following the transient increase in the systolic power of the heart there is a dilatation of the ventricle.

Adrenalin produces, in the cat especially, marked salivation. There is secretion of tears, increased activity of most mucous membranes, increased flow of gastric juice and bile (not of pancreatic juice), and erection of the hair.

The results of adrenalin injection come even after division of the sympathetic, and the effect is said to be at the myoneural junction (Elliott) or the so-called receptive substances of Langley. Repeated intravenous injections tend to produce necrosis of the media of the blood vessels and degenerative changes in the arteries. The relationship to arteriosclerosis might be studied with advantage. Subcutaneous injection is followed by few effects; sometimes there is hyperglycemia and glycosuria,

with increased nitrogen elimination; not, however, if the glycogen depots have been depleted. Intramuscular injection has more marked effects. Large doses may produce depression, torpor, paralysis of limbs and muscles of respiration with asphyxia. If fed by mouth the active principle is absorbed so slowly that it is rapidly destroyed. Meltzer found that the active principle was destroyed by cerebrospinal fluid and inactivated by formaldehyde. The amount of adrenalin found in the suprarenal vein is small—one part in a million. (Hoskins, McClure, O'Conner.) Cannon obtained inhibition of the intestine by a solution of one in twenty million. Janeway and Park obtained inhibition of a strip of the coronary of the sheep by a solution of one in fifty million.* Violent emotion, fear, according to Cannon, produces a hyperadrenalinemia and can lead to glycosuria, due to rapid conversion of glycogen to sugar; this has recently been disputed by Stewart and Rogoff. The adrenalin glycosuria may last for days. Effects of adrenalin are like those of the Claude Bernard puncture and are due to stimulation of the splanchnics. After splanchnic section, the Claude Bernard puncture causes no glycosuria. The adrenals affect the liver through the nerve centers and the Claude Bernard puncture is not effective after the removal of the adrenals. Adrenalin is necessary for the proper function of the splanchnic. Sensory stimuli may reflexly stimulate the splanchnics and lead to adrenalin glycosuria. Pemberton and Sweet found that the removal of the adrenals caused a flow of pancreatic juice. Herter and Wakeman found that swabbing the pancreas with adrenalin caused glycosuria. The effect is through the liver and carbohydrate metabolism seems to be regulated by the interaction of the adrenal and pancreas on the liver cell.

Adrenalin is used to check hemorrhage, locally by injection into the proximity of the wound; it is frequently combined with a local anesthetic because, through the vasoconstriction, the anesthesia is increased, and by preventing absorption it prolongs the effect of the anesthetic. It is used also in nasal inflammation. Adrenalin is a good uterine hemostatic, and Neu also found it of value in the production of labor pains. It sometimes will induce fever; it relieves bronchospasm.

Dose and Method of Use.—A solution of adrenalin chloride is the preparation used; usually a 1-1000 solution in physiologic saline; maximum intravenous dose is variously placed at 5-15 minims. Lethal dose is said to be 1 mgm. per kgm. of body weight.

The thyroid, hypophysis, and adrenals form an organic group. Their effects are similar and their action synergistic. This is especially true of the pituitary and adrenals. They both relieve bronchospasm. The effects on the bowel, however, differ; adrenalin relaxing, and pituitrin contracting the smooth muscle of the intestine. Both pituitrin and adrenalin seem to influence osteomalacia favorably.

The Pineal.—The pineal is one-half the size of the pituitary. It is in the roof of the third ventricle and lies between the anterior corpora quadrigemina. It is larger in the child and in the female. Its secretion is said to be diuretic and to exert an inhibitory effect on sex development. Disease of the pineal is usually associated with sexual precocity. It is made up at first of epithelial cells. It reaches the maximum development at seven years. There are no true nerve elements; it regresses after puberty. "Brain sand" is said to be formed here. Injection of its extract causes first a fall in blood pressure and diminution in kidney volume, later a rise in blood pressure and increase in kidney volume. It causes contraction of the uterus and is said to be a galactogogue. Foà, working on fowls, and Sarteschi, on rabbits, found that after extirpation of this gland there was early development of sex and the skeleton; tumors of the pineal cause the same changes, resembling in this tumors of the adrenal cortex and of the testis. The sex effects are said to be the result of hypopinealism, while hyperpinealism is said to lead to adiposity. The administration of pineal extract produces precocious sex development, especially in males. The effects of this gland have not been definitely worked out. Dandy got no bad effects from total extirpation. Timme holds this gland responsible for some of the myopathies.

The Thymus.—Originally a gland of epithelial structure, it later resembles a lymph node. It is an organ of great importance, especially in the prepuberty period (Gudernatsch). Basch, Klose, Vogt, and Matti have done most of the work on this organ. It is largest at birth, and atrophies after puberty. It seems to play a part in the condition known as status lymphaticus. Fasting reduces its size. Thymectomy softens the bones, increases the excretion of calcium, causes muscular weakness and tremor. According to Klose and Vogt, it increases the rate of development of the sex glands (this was confirmed by Paton). Removal of the posterior lobe of the pituitary retards this precocious sexuality. Castration leads to the development of a large thymus, even in mature male animals, not, however, in females. In hibernating animals the thymus is said to persist throughout life, enlarging at hibernation, due to storing of fat by the thymic cells. Removal of the gland may also lead to disturbances in nutrition and growth and to psychic defects, and also to increased irritability of the peripheral nerves. Thymus is thought to play a part in the synthesis of nucleic acid. If the thymus is small, the thyroid, too, tends to be atrophic. Some cases of Basedow's disease are associated with a large thymus, which is of bad prognostic significance. Thymus extract, on the other hand, is sometimes of value in Basedow's disease. The thymus has been used in developmental disturbances, in infantilism, in rachitis, but its effects are doubtful.* Myasthenia gravis is said to be due to disease of the thymus.

Sex Glands.—Their importance is shown by the failure of the secondary sex characters to appear after castration of the young. Castration leads to characteristic growth anomalies. Tandler and Grosz described two types of eunuchs—tall, long boned, lean types, and short, fat individuals with broad hips. The deposition of fat is chiefly in the lower abdomen and nates. There are also psychic

*Sergent has described a white line produced by passing a blunt object over the skin. When present it is said to indicate marked adrenalin deficiency.

*Marshall maintains that there is no relation between the thymus and rickets (Proc. Ropal. Soc., London, 1914, lxxxviii, 68).

changes in these individuals—mental hebetude, indolence, and lack of initiative. Similar phenomena occur after accidental castration of adults and are due to loss of sexuality. The cells of Leydig, or the interstitial cells, are the important source of the internal secretion of the testis. It is not obtained from the gonads. After castration in the child, the prostate and seminal vesicles remain undeveloped. The secondary sex characters are absent. The epiphyses remain separate from the shaft. The bones are longer and very delicate, the sutures of the skull are slow to ossify. There is also mental infantilism. The thyroid is small; the suprarenal cortex, the thymus, and the pituitary are increased in size. Castration after maturity leads to regressive changes with atrophy of the prostate, but the chief effects are metabolic. There is deposition of fat, although there seems to be less tolerance for dextrose. In the stag, the antlers remain undeveloped. After experimental ligation of the vas, desire is present, secondary sex characters are present, too, although the seminiferous cells atrophy; this shows the importance of interstitial cells. Steinach transplanted the testis of a young animal to another part of the body. The animal developed normally; the sex cells were absorbed, but the interstitial cells remained. He also found that an ovarian transplantation in a previously castrated male takes, and both types of cells survive. The secondary sex characters do not develop; the animal shows female character and is sought by the male like a female.

In rabbits, with one testis removed, tying of the vas of the remaining one leads to hypertrophy of interstitial tissue. Tumors of the interstitial tissue of the testis are frequently associated with increased growth and premature development of sex. The interstitial cells are not destroyed by the *x*-ray.

In the ovary, the important internal secretion is that of the corpus luteum. This is marked throughout the pregnancy. Oophorectomy leads to the development of small uterus, absence of menses, and the male type of trichosis. Loewy and Richter found that ovariectomy leads to diminished consumption of O_2, and ovarian treatment not only restores O_2 intake to normal, but even increases it. The same effect is seen in castrated males, therefore the ovary increases oxidation in the body. If castration is done later in life, there is atrophy of the mammæ and cessation of menstruation. There is a slight increase in the size of the pituitary and a tendency to adiposity. Again, tumors of the ovary lead to premature development of secondary sex characters in the female.

Effects of Ovarian Extract.—The intravenous injection of an extract of interstitial cells inhibits the normal rhythmic movements of the uterus and diminishes its tone. There is a fall of blood pressure and diminished kidney volume. Corpus luteum extract, on the other hand, causes contraction in the quiescent uterus, and no effect on blood pressure or kidney volume. Immersion of a uterine strip in liquor folliculi causes increased contraction and tonicity. In lactating animals extract of corpus luteum causes an outpouring of milk.* It resembles pituitrin in this action. MacKenzie found that this did not occur with an extract of ovary minus the corpus luteum. Feeding corpus luteum to white rats causes a laying on of flesh and retention of nitrogen. Corpus luteum favors the development of the mammæ. According to Schafer, heat in animals is not due either to Graafian follicles or corpus luteum, but after ovariectomy heat can be induced by grafting ovarian tissue.

Bowne and O'Donoghue found that in virgin rabbits, if Graafian follicles are ruptured the mammæ develop. Ott and Scott found marked development of the mammæ and milk secretion in virgin rabbits after subcutaneous injection of corpus luteum extract. If the corpora lutea are destroyed in the pregnant animal, the growth of the mammæ is arrested. Corpus luteum is said to influence the formation of the decidual membrane and fixation of the embryo. Frankel found that if in rabbits the corpora lutea are destroyed early in pregnancy, the embryo does not adhere to the mucous membrane and ceases to develop.

Leo Loeb found that mechanical stimuli can produce decidual membranes and uterine hyperplasia, if corpora lutea are present, but not if corpora lutea are absent. Loeb also found that extirpation of the corpus luteum accelerates the bursting of the ripe Graafian follicle, and is therefore conducive to ovulation. The presence, therefore, of the corpus luteum militates against ovulation. Menstruation is allied to ovulation, and the discharge of ova from ripe follicles is designated as a missed opportunity of impregnation. The fact that it begins at puberty and ends at the menopause is an expression of this relationship. Menstruation is said to be due to the action of the interstitial cells of the ovary.

The menopause symptoms, involution of the genitals, vasomotor symptoms, flushing, and nervousness are too well known to require further discussion.

Replacement therapy is of little value in men. The reports of effects on women vary. Most women find relief from the ingestion of ovarian extract, and since the investigation of Frankel, corpus luteum also has been used. Here, too, as in the case of the testis, the interstitial cells seem to be the carriers of the internal secretion. In women the ovaries seem to accelerate metabolism; hence the increase in weight of castrates and at the menopause. On the whole organotherapy is not so effective here as in the case of the thyroid.

Brown-Séquard, who was the father of organotherapy, has not been confirmed in his statement of the value of testicular and ovarian extract as vitalizing agents. Sequarine and spermine were the preparations used. Spermine isolated by Poehl was said to increase the oxidation processes and prevent muscular fatigue, and to aid in cases of impotence. Zoth and Pregel, by means of the ergograph, obtained evidences of lessening of fatigue. Burgi and Traczewski experimented with neosequarine and testiglandol, and found that they stimulated the activity of frog's heart.*

Ovarian extract and corpus luteum extract help

*Galactagogue principles are present in the corpus luteum, in the involuting mucous membrane of the uterus, in the lactating gland itself, and in the pineal.

*The sex glands have definite relationship to the thyroid pituitary, adrenal, cortex, thymus, and pineal. Theoretically, the sex glands are more influenced by the other glands than those are through either testicular or ovarian extract.

to remove flushes and acroparesthesias. There seems to be a certain relation between water retention and menstruation, and Burgi thought that the inhibition of diuresis was due to the sex glands. Pituitrin and thyroid diuresis, he found, could be inhibited by ovoglandol, testiglandol, and neosequarine. Quincke's edema and migraine are possibly due to disturbances in the water balance in the body, and the frequency of both of these at the menstrual period seems to point to diuresis inhibition as a factor. Pituitrin has been suggested as being possibly of service at such a time. Ovariectomy has been reported of benefit in osteomatacia.

Internal Secretion of Uterus.—Menstruation and ovulation may be dependent upon an internal secretion of the uterus. The latter was said to promote the growth of corpus luteum. Carmichael and Marshall found, however, typical development of the ovaries, even without the uterus. MacKenzie found that extract of the involuting uterus caused a free flow of milk from the incised nipple of the lactating animal.

Parathyroids.—The parathyroids, four in number, may be separated from the thyroid. The upper are dorsal and above, the lower are more medially placed, but more outside the thyroid. Their removal causes tetany and other nervous phenomena, such as increased reflexes, spasms, stiffness, increased irritability of nerves, tachycardia, vomiting and diarrhea, wasting, loss of hair, failure of calcification of the growing incisors (enamel defects). The effect on the nervous system is on the lower motor neuron and is not removed by ablation of the cortex or section of the posterior nerve roots. In section of the cord, the symptoms disappear below the level of the section.

Some relief has been obtained in the case of these experimental animals by the injection of thyroid or parathyroid. One gland seems to be enough to prevent onset of symptoms, and homologous transplantation is also of service. Pregnancy and flesh diet favor the onset of tetany. The young seem to suffer more from the removal. The parathyroids are antagonistic to the thyroid. Tetany occurs in pregnancy, in acute infections, in the new born, and in some gastric cases. Thomsen's disease, paralysis agitans, chorea, epilepsy, and eclampsia were said to be due to the disease or deficient activity of these organs. The secretion is said to be increased in myatonia and myasthenia gravis. The changes in the hair and the nails, the bones and the teeth which occur after parathyroidectomy are said to be due to altered metabolism, especially of calcium (increased excretion). The effects of injection of the parathyroids have not been adequately studied.

The nature and the mode of action of the parathyroid substances are also not definitely known. The active principle has not yet been isolated. It seems to inhibit the excitability of the nerve cell. The parathyroids are supposed to be detoxicating organs. The deficiency symptoms are not removed by oral feeding, and implantation also has not been successful.

The work of Erdheim abroad and that of MacCallum and Voegtlin in this country have added greatly to our knowledge of this organ. A parathyroidectomized animal loses its calcium rapidly. The parathyroids seem to favor calcium retention. Tetania parathyreopriva can be ameliorated by the administration per os, subcutaneously, and intravenously of calcium salts. MacCallum and Voegtlin used the acetate and lactate of calcium. They found the injection of the gland extract also of value, leading to increased calcium content of the blood. The results, however, are not permanent, and it might be that the calcium simply acts as an antispasmodic. Administration of thyroid seems to be beneficial in some cases.

Pancreas.—The internal secretion of the pancreas is concerned chiefly with carbohydrate metabolism. The pancreas is the antagonist of the adrenals, pituitary, and thyroid. Pancreatic internal secretion favors the conversion of glucose to glycogen, or inhibits the transformation of glycogen to sugar. Cohnheim thought that the pancreas produces an activator of a glycolytic enzyme, present in muscle. The islands of Langerhans seem to be the chief source of this internal secretion, and Falta speaks of the pancreatic island apparatus. The islands of Langerhans vary in number. There are 10 to 20 islands in each mgm. of gland, and all told there are about 1,000,000 islands in man.

Mehring and Minkowski found that depancreatization causes diabetes, but simple tying of the duct does not, because, according to Sbolew, it does not affect the islands. If the atrophic gland is removed after tying, diabetes does develop. Transplantation removes the diabetes and the removal of the transplant produces diabetes. That these islands are diseased in diabetes has been shown by Weichselbaum, Opie, and others. Pancreatic treatment is of little value. In complete removal of the gland, we get the well-known dextrose nitrogen ratio of 2.8 to 1.

With a protein diet the sugar rises and falls with the nitrogen. Carbohydrates pass out as dextrose. Levulose may restore some glycogen. There is a hyperglycemia and death takes place from inanition or coma. Paton found no glycosuria after depancreatization of birds, but there was hyperglycemia and the subsequent administration of adrenalin caused glycosuria. The hormone of the pancreas is called insuline. Pancreatic extracts have no curative value in this condition.

If the blood of a normal dog is allowed to circulate through the vessels of a depancreatized dog, it will prevent diabetes; it evidently furnishes the missing hormone or chalone.

Carlson found that a depancreatized pregnant bitch has no glycosuria, as long as the fetuses are there to supply the hormone. Hedon showed that this substance was active only after the pancreatic blood had passed through the liver. In pancreatic diabetes, the glycogen of the leucocytes is increased (stored there), because the liver cannot store it. The glycolytic power of the blood is not interfered with.

It is most likely that the agent is a chalone inhibiting the formation of glucose from glycogen; hence in this disease glycogen cannot be stored. In the excised liver, the glycogen is rapidly changed to dextrose; the pancreas normally inhibits this change.

Fourth ventricle puncture, stimulation of the

splanchnics, and the injection of or swabbing of the pancreas with adrenalin causes diabetes. In depancreatized animals, the injection of adrenalin increases the diabetes. Adrenalin glycosuria may be prevented by pancreatic extract due possibly to its effects on the permeability of the kidney. In depancreatized dogs ligation of the adrenal vein is said to prevent glycosuria.

Pilocarpine is said to prevent adrenalin glycosuria by stimulating the vagus ends going to the islands. Loewi found that after removal of the pancreas, adrenalin instillation into the eye dilated the pupil. This does not occur normally, but does occur in human diabetics.

The removal of the thyroid tends to prevent both bulbar and pancreatic diabetes. Removal of the parathyroid tends to facilitate its development. The increased tolerance for carbohydrates in myxedema, hypopituitarism, and hypoadrenalinism is due to the effect of the pancreas.

The Internal Secretion of the Alimentary Tract.—Bayliss and Starling, in 1902, found that injection of the extract of the mucous membrane of the duodenum caused an increased flow of pancreatic juice. This substance was obtained by boiling with diluted hydrochloric acid and neutralizing. The filtrate contained a substance which they called secretin. Duodenal extract also increased the flow of bile and enteric juice. In the cow the intravenous injection of duodenal extract produces a discharge of the secretion of the posterior lobe of the pituitary into the cerebrospinal fluid. Pawlow has obtained what he calls a gastrin from the mucous membrane of the pylorus. These hormones are said to act directly on the cells.

Placenta.—According to Halban, placental extract stimulates the growth of the mammæ; not, however, the milk secretion. This is improbable, because virgins and men may also develop at times large breasts. Injection of placental extract inhibits the galactagogue effect of pituitrin or corpus luteum. Both placental and fetal extract inhibit milk secretion and the milk does not begin to form until the influence of the placenta and the fetus is removed—a striking example of teleology in nature.

Spleen.—Extract of the spleen is said to activate trypsin. The spleen plays a large part in the disintegration of the red cell. Red blood cells are found in all stages of degeneration, and there is a large deposit of iron in the spleen in pernicious anemia. According to some, it is also the site of formation of red blood cells. The spleen takes part in the synthesis of uric acid.

Organotherapy has been attempted with extract of the bone marrow, of the spleen, and of the bowel; thus far, however, with little success. We may say that probably all organs produce substances which influence in some way or other the body metabolism. With increasing advances in our knowledge, they will be isolated and made use of for therapeutic purposes.

REFERENCES.

The literature on the internal secretions has become so vast that one hesitates to give a detailed bibliography. The works, however, of Biedl, Schafer, Paton, Gley, Falta, Harrower, and Sajous should be consulted.

PHYSICAL EXAMINATION OF APPLICANTS FOR INDUSTRIAL POSITIONS;

WITH RESULTS OF THREE HUNDRED EXAMINATIONS.

By CARL SCHEFFEL, Ph.B., M.D.,

BROOKLINE, MASS.

This review of physical examinations is based on the examination of three hundred males between the ages of sixteen and sixty-two applying for positions at medium, but rather hazardous labor. The applicants include all classes and many nationalities. The majority are of foreign birth, and as a whole the group is comprised of many who have never undergone physical examination before for similar purposes.

The object of examining these applicants was three-fold. In the first place, industry is commencing to realize the value of placing the right man in the right place if possible. It is unfair to the employee and unfair to the employer to place a man at work for which he may to all outward appearances seem physically fit, but who upon even superficial examination shows defects that would greatly jeopardize his future well-being or safety. A man suffering from greatly defective vision is not fit to work about nails or splinters any more than the man suffering from tuberculosis is fit to work at a dusty occupation. Bringing the man and suitable employment together should be one of the main objects of the physical examination of prospective employees.

The second aim of physical examination is to prevent infectious or contagious diseases from being knowingly carried into the workroom, there possibly to be disseminated to the danger of others. It should be the duty of the employer to protect his employees against the hazards of contagion and infection during working hours. A new employee continuously hacking and coughing is not only obnoxious to his fellow employees, but may be capable of spreading tuberculosis as well. So also may the harborer of a syphilitic sore throat spread his disease through the medium of the bubbling fountain.

Another object of physical examination of prospective employees in these days of rising insurance costs is the elimination of undesirable risks. An applicant with a hernia not supported by a suitable truss, if put to work at lifting or straining, will almost certainly become an operative case with its attending loss of time and expense to the insurance carrier sooner or later. Likewise with a man having greatly defective vision. Place him where eye injuries are common, or where the workroom is littered with objects upon which he may cut himself, he will almost surely become injured in a short period of time. Employing a man with vision of 20 50 or less is certainly burdening the insurance carrier with a bad risk and is distinctly unfair to him unless this defect is corrected by glasses.

The desirability of physical examinations for applicants for industrial positions is apparent. Proof that such examinations are of benefit both to the employee and employer may be deduced from the fact that very few of the former refuse to be examined when approached in the proper spirit, and

that wherever such examinations have been utilized by the latter they have been continued and extended in scope.

The experience of most examiners has been that the number refusing examination is negligible. While no exact figures are at hand as to the number of actual refusals, out of this series of three hundred cases not one refused to go through with the examination after having reached the examining room.

The refusal of a reasonable physical examination on the part of an applicant denotes stubbornness and may be viewed from an angle quite independent of the main purposes of these examinations. An applicant for a position is probably most docile before he is actually employed. If he is refractory to routine rules and regulations before he is employed it is a pretty certain indication that he will be more so after obtaining employment.

Of the three hundred applicants examined, the following is a table of the more prominent defects found in so far as they bear relation to the employment sought.

Number examined	300
Tuberculosis	1
Flat foot	1
Right inguinal hernia	2
Scrotal hernia	1
Varicocele	1
Enlarged inguinal glands	13
Heart murmurs	4
Active infection of hand	1
Ankylosed finger joints	5
Partially amputated fingers	8
Destroyed tendon function	3
Vision less than 20/40	5
Vision less than 20/50	6
Total number of gross defects	51

In addition to these defects there were thirty-three applicants who had been in this country from four to eleven years who could not read the English alphabet to have their eyes tested by the ordinary Snellen's test type.

The scope of these examinations extended from head to foot in a general way, but record was kept only of those defects related to the performance of the duty required of the applicant in case he was accepted for employment. The mentality of all applicants was carefully surveyed with the view of eliminating feeble-minded, imbecile, and degenerate types. None was found in this series of examinations. While admittedly the teeth and throat have an important bearing on the general health of the applicants, records of their condition were not kept. However, it may safely be stated that not one had teeth which were not defective. In the throat syphilitic patches were especially looked for, but none was found in this series of cases.

Considerably more importance was laid on the eyesight of applicants because a reasonable degree of vision is necessary for the industry they sought to enter. Vision of 20/40 and less greatly increases the accident hazard, and it is an established fact that poor eyesight greatly diminishes productive power. All those with defective vision were advised to procure glasses, and it is sad to note that many of the younger men would rather forfeit employment than wear glasses, even though with their defective eyesight they become a danger to themselves and to others on the public highway as well as in the workshop.

In examining the chest, early signs of tuberculosis were especially sought for, and one case detected. Heart murmurs were found in four cases, but inasmuch as no other symptoms accompanied them the persons were given work for which they were fitted. Blood pressure was taken in all applicants over fifty years of age and none found excessively high. Rapid, nervous, and palpating heart action was frequently met with in those never examined before.

The abdomen was particularly examined for hernias and tendency thereto, enlarged livers, and evidences of old adhesions which might interfere with their work. Outside of the hernias and a rather large number of enlarged inguinal glands, nothing of special importance was found in this series of cases.

Inasmuch as nimbleness of hands and fingers is of considerable importance in this particular industry, special attention was given to the condition of the hands. Out of the three hundred examined, sixteen, or 5.3 per cent. had received previous incapacitating injuries to their fingers. Of these sixteen, eight had partially amputated fingers, five had one or more ankylosed joints, and three had some loss of tendon function. Of those who were given employment with partially amputated fingers, none have as yet received major second injuries. In fact these men have become most cautious employees so far as accident prevention is concerned.

Conclusion.—A study of the above outline should convince anyone of the practicability of this work. The benefit derived therefrom is shared by both employee and employer. A physical defect by no means precludes employment; but it does prevent the applicant from being placed at work for which he is not fit and which would become a drudge to him because of his defect. Then again, a physical examination may, and often does, acquaint the examined with some defect that he did not suspect before, and so gives him opportunity to seek early and proper remedial measures.

On the other hand, physical examination protects the employer from unwillingly undermining the health of his employee by placing him at work for which he is not physically fit. It also protects him from assuming undue risk of industrial accidents. How many of the above mentioned hernia cases would eventually result in operative cases at the expense of the employer or insurance carried is difficult to predict, but from all available records it may be safe to state that all would become dangerous risks sooner or later. The same holds true as regards defective vision. Workmen with vision below 20/40, if uncorrected by glasses, are bad risks to themselves and others if allowed to work about sharp raw material, machinery, tools, and other matter littered about the floors of many industrial establishments. Just how many industrial accidents are directly or indirectly due to defective eyesight is impossible to tell, but undoubt-

edly they are far more numerous than suspected. At any rate, an employer placing a man with a vision 20/50 or less on work where he may stumble, scratch or cut himself, is certainly courting accident to the employee and expense to the insurance carrier.

While physical examination of prospective employees is far from universal, it is being adopted by many large industries. That it is a good investment from a business point of view is conceded by all who have adopted it and systematically utilized its results. That it is a humane and educational procedure should be appreciated by both employee and employer.

THE SUGAR TREATMENT OF TUBERCULOSIS.

By ALEXANDER STERLING, M.D.,

PHILADELPHIA.

My object in presenting this paper is to put before the general practitioner, who has very little time for research, the evidence of saccharose experimentation offered by many different investigators and my personal clinical findings of the effect of saccharose (Lo Monaco's technique) in tuberculosis and to stimulate clinical interest along this line.

The value of sugar in disease was recognized long ago. Underhill and Closson[1] in their article on "The influence of subcutaneous injection of dextrose upon nitrogen metabolism" have shown from their experiments in the Sheffield Laboratory of Physiologic Chemistry the ability of the body to utilize dextrose after subcutaneous injections. The same observers further suggested that injections of sugar may play an important rôle in connection with subcutaneous nutrition from a clinical standpoint on account of the great power of the animal body to utilize sugars given subcutaneously.

Gaulston[2] in his paper on the beneficial effect of the ingestion of cane sugar in certain forms of heart disease, illustrating that dextrose is capable of nourishing the heart muscle in a most wonderful and peculiar manner cites F. S. Lock of Kings College, London, who has kept the excised mammalian heart beating for 91 hours after the death of the animal from which the heart was taken, by means of perfusion with solutions of dextrose carried out daily; the regularity of the heart beats was remarkable and at the end of that time it was used by Professor Halliburton to demonstrate to a class of students.

Sir James Sawyer[3] in his notes on the therapeutics of sugar, commenting on Gaulston's clinical findings, states that he had also used cane sugar with success for the last 10 years in anemia and wasting diseases, and in persons with neurotic manifestations, and found that the patient increased in weight and power; that sugar appears to act both as a nutrient and also as a tonic, the continued administration of which in debilitated and relaxed conditions of the body imparts strength and vigor with permanent effect.

D. Lo Monaco[4] remarks upon the favorable action of sugar in reducing suppuration and hastening healing of wounds. He also found that while small injections of saccharose increased the secretions of the milk in the nursing woman, large doses decreased it, and furthermore if the woman was tuberculous her night sweats and expectoration also decreased, accompanied by a remarkable gain in weight. These results suggested to him the use of saccharose to reduce expectoration in pulmonary tuberculosis. His pupil, Luccherini, reported excellent results; he stated that the secretion, expectoration, and night sweats subsided, and many of their patients had no return of their expectoration after 40 to 50 injections. Even the moist râles subsided and some of the patients returned to work. Lo Monaco further states that the sugar treatment was of no avail in tuberculosis with grave intoxication, but acted best when the acute state was past and the main symptoms were profuse expectoration and night sweats with great debility and emaciation. In such cases the saccharose injections may effect actual resurrection, improvement being manifest by the tenth day. This treatment is very useful also in cases of dilatation of bronchi, or asthma, and in emphysema.

Raimondi[5] found that injections of saccharose by Lo Monaco's technique gradually reduced the expectoration and cough but did not modify the fever. He found it valuable as a vasoconstricting agent in reducing the tendency to hemoptysis. The general health of the patient improved but the pulmonary process did not seem to be influenced.

Picodo's results in nine cases of pulmonary tuberculosis with Lo Monaco's method were rather disappointing.[6] In a few the cough and expectoration diminished; in one the sputum showed blood for the first time, in another the blood-stained sputum seemed unmodified; but the great advantage of this treatment was that the cough and expectoration might be reduced without injuring the stomach.

Bodmer,[7] commenting on the result of his researches on the absorption of subcutaneous injections of saccharose in tuberculosis found that in his fourteen patients all the saccharose was eliminated by the kidney in 48 hours. The sugar was eliminated without being inverted. The symptomatic effect of reduction of exudation was pronounced with striking reduction in the amount of sputum. The action was most evident in comparatively recent cases. He had never seen such a pronounced effect from any drug, and the only explanation was that of a vasomotor influence.

Sir Clifford Allbutt has said that the new birth of medicine is nothing less than the enlargement of medicine from an art of observation and empiricism to an applied science founded on research. Therefore I think the modern enternist should not hesitate to utilize certain therapeutic measures, especially when the investigators in physiological chemistry laboratories are demonstrating their value.

Why the American internists did not accept the suggestion of the result of the experiments of Underhill and Closson in May, 1906, long before Lo Monaco wrote that "injections of sugar subcutaneously are demonstrating a great power in connection with subcutaneous nutrition," is something which I would not undertake to explain.

My own results in six cases of tuberculosis with

saccharose medication are rather confirming and very encouraging. It is a strong supportive therapeutic measure in conjunction with other standard measures.

The tuberculosis patient feels strong; though he may have an elevated temperature he is not depressed, he gains in weight from 3 to 10 pounds. In my patients there was a marked gain in weight only in the first two weeks from 3 to 10 pounds; after that they were either stationary or gained very little. Expectoration and night sweats ceased after six to eight injections; the cough was dry and less troublesome.

I would advise institutions treating tuberculous patients to adopt the saccharose injection as a routine therapeutic measure without fear, it being absolutely harmless. Any dependable drug store that is making ampoules for intramuscular injection can make an ampoule containing saccharose, 5 grs. in sterile distilled water, 5 c.c. The ampoule of course must be sterilized by the maker ready for use. Injections to be given daily or every other day. Personally I prefer the gluteal region for all my subcutaneous injections. There is very little pain if one develops the art of injection medication, and if the hypodermic syringe (of 10 c.c. capacity) is heated before use, one will most likely never have an infection.

Case I. Private J. N., male, aet. 30 years. Acute pulmonary tuberculosis; sputum repeatedly positive; T. 100° to 101°, P. 90 to 100. Normal weight from 125 to 128 lbs.; present weight, 113 lbs. Constant cough, marked expectoration, night sweats. He has not worked for 3 months. Had 24 saccharose injections besides forced feeding, and other systematic medication. He gained in weight to 123 lbs., coughs very seldom, no night sweats, no expectoration. He feels strong and has been working for the last 4 months. The sputum is still positive tuberculous.

Case II.—Ch. G., physician; moderately advanced pulmonary tuberculosis for 3 years; returned to Philadelphia after a stay in Arizona for 1 year. Temp. 99°, P. 100. Had very marked expectoration, 3 to 4 ounce cup every night. After six injections the expectoration almost entirely ceased. Doctor G. says that he had no expectoration after the fifth injection, that his cough was absolutely dry; he was afraid he would get exhausted from the dry coughing (as he was under the impression he must expectorate), but the cough was more or less improved and he felt much better.

Case III.—From O. P. D. Clinical Medicine, Jefferson Hospital. J. K., 36 years old, male, moderately advanced tuberculosis; cough, with marked expectoration, night sweats, great debility, sputum repeatedly positive. T. afternoon, 100° to 102°, pulse 100 to 140. The patient had 24 injections, and now feels stronger and has gained 5 lbs. in the past 3 weeks. He has no expectoration, no night sweats, some cough, temperature is normal in the morning, and 99.5° to 100° at 3 P. M.

Summary. 1. In this series of patients with tuberculosis the subcutaneous injection of saccharose had very little if any effect upon the progress of the fever.

2. Night sweats and expectoration ceased almost immediately.

3. The reduction of the cough was not in proportion to the reduction in the expectoration, hence a dry and distressing cough might be present in the beginning, but it was more or less controlled later.

4. There was a marked gain in weight and strength with an amelioration of the toxemia and its depression.

THE FORCES OF NATURE.

By B. LEMCHEN, M.D.

Chicago, Ill.

Physician to the Chicago State Hospital.

The forces of nature are three in number, namely, physical, chemical, and biological. They differ in that, in physics, the forces are liberated by movements of matter, like winds, etc.; in chemistry the forces are liberated by the rearrangement of the molecules in matter, as in a chemical reaction; in biology the forces are liberated and used in metabolism, reproduction, movement, and special functions. The cells in the stomach will liberate hydrochloric acid from an alkaline fluid—the blood—which never happens in inorganic chemical processes. I said liberate because, in careful analysis of matter, we find it to consist of molecules which are composed of atoms which, in turn, are composed of electrons, which are nothing more than forces. The claims of the theologians that a force existed before matter which controls matter and, to a great extent, the actions of men, is scientifically true.

This planet of ours once was composed of electrons or forces which the surrounding atmosphere has cooled and compressed into atoms and molecules which constitute matter, retaining the forces and liberating them in the inorganic world by movement and molecular rearrangement of matter. During evolution of matter, substances with large molecules were formed, which we call protoplasm, and when our planet reached a lower temperature several of those protplasmic molecules united and formed the living cell. The cell, owing to its large molecules, contains a great number of electrons which adapt it to its functions.

In inorganic matter we find some of the elements existing in different forms, due to atmospheric conditions during the stage of forming, for instance, carbon exists in the diamond, coal, and graphite; so it must have happened in the organic world and the primary cells formed by thousands, consisting of different molecular arrangements, some of them even containing elements that others did not.

Antagonism between cells apparently developed at an early stage of evolution owing to the many differences in their construction, the rapidity of their multiplication, and the limited food supply.

Several cells may unite to combat others as happens to-day in chronic infections like tuberculosis, where the giant cells are formed; and it was in this way that the multicellular organisms were formed. During the stages of evolution, mixed breeding surely must have taken place and in this way the

different animals, including man, apparently developed. While it is hard to trace man to the unicellular organism and to different cells, still the possibility of it must be admitted. This will account for the difference in susceptibility to diseases in different individuals and the different reactions of the insane.

As I have stated before (MEDICAL RECORD, Feb. 1, July 12, 1919, and June 29, 1918), mind itself is nothing but a force which is present in all matter, but it differs in organic matter owing to the large size of the molecules with the great number of electrons, so that many functions are possible.

In the unicellular organisms the forces are used by each cell as created by the activities of its molecules. In the multicellular organisms the forces are given off by the cells and special cells known as neurons collect, transmit, modify, store, compare, and project the same forces for the benefit of the entire organism. The higher in the scale is the organism, the more the force is modified and stored till we reach man and find that he possesses more of the cells that are known as neurons than any other animal, in proportion to the size of his body.

It was through the struggle of existence that the multicellular organisms developed from the unicellular organisms. It was through the struggle of existence that special cells in multicellular organisms learned their special functions. It was through the same struggle of existence that man's brain has so wonderfully developed. By knowing these laws we can understand the rôle heredity and environment play in an individual in health and disease.

Disregard of those facts is responsible for the enormous increase of the insane and criminals, and it is right here where the cooperation between the minister and physician will do good in educating the people as to the right mode of living. When some one listens to the talk of the so-called humanitarians, telling us that the insane are not responsible for what they are doing, that restraint must be abolished in the hospitals for the insane, and advocating the discharge of many inmates in institutions for the insane and criminals, do they realize that nothing will deteriorate a mind more than for its possessor to know that he can do what he pleases without being punished, and that he can get what he wants without working for it?

When will the so-called humanitarians learn that removal of restraint from State institutions will be appreciated when something better is found to take its place. I read only recently in a medical journal a report of a psychopathic hospital on the results of the treatment of postinfectious cases following the last epidemic of influenza, and, if I understood it right, the number of cures was about 15 per cent. The author of the report said the reason so many patients did not recover was because they were dementia precox cases. Very well, but what makes dementia precox? I said before that dementia precox is due to either an inherited or acquired weakness of the neurons. May not our modern treatment have something to do with it? A modern psychopathic hospital surely has removed all restraint, but the delirious patient sees and hears the most terrifying things and tries to run away or defend himself to-day just as he did years ago when we had restraint.

The way a delirious patient is prevented to-day from injuring himself or others is by placing him in hot baths or packs or by giving him sedatives, and all these measures have a tendency to weaken the neurons or, in other words, we take a patient whose neurons are already weakened by disease and weaken them still more by our treatment. Force is just as much a part of the cells as are the elements and we can have cells that will not show any anatomical changes and still not function right. In tetanus or shock a person may die and no anatomical changes be found. There are many deaths that cannot be explained on anatomical findings at the autopsy which must be due to disturbance of functions. In fact, in practically every disease we have predominant symptoms before anatomical changes can be demonstrated by physical examinations. The same is true in insanity. The chronic form, like dementia precox, is a functional disorder of the neurons brought about by inheritance or acquired weakness of the neurons, and if we want to reduce the number of the insane we must see to it that the insane do not propagate, that normal children are not raised together with abnormal, that pregnant women receive proper care during their pregnancy, that children get proper care during their infancy. Much can be accomplished by taking the control of our hospitals for the insane from the politicians and transferring it to well-trained physicians.

Medicolegal Notes.

Medical Evidence—Cause of Injury.—A question to a medical witness calling for the history of the accident as given him by the plaintiff more than a year after the accident occurred is properly excluded, where the inquiry is made under the pretext of offering evidence of the foundation of the physician's opinion for the purpose of violating the general rule excluding prior statements of the party.—Boulanger v. McQuestin, New Hampshire Supreme Court, 106 Atl. 492.

Course of Treatment—Practising Without License.—In an action on an alleged agreement whereby the defendant promised to pay $300 for a six months' course of physical or medical treatment from the plaintiff corporation it appeared that the defendant found he was too weak to receive the treatment, and notified the plaintiff he could not fulfill his contract. The New York Appellate Division holds that he was relieved from liability to pay the plaintiff the contract price, having received no consideration. It was also held, two justices dissenting on this point, that a corporation which gave a course of graduated exercises, advertised to stay the hand of time and bring back the days of boyhood, was not so engaged in the "practice of medicine" without a license, in violation of New York Public Health Law, section 160, subdivision 7, as to preclude its recovery on a contract to furnish such a course of treatment. Judgment for the plaintiff was reversed and the complaint dismissed.—Samuel v. Hains, 187 App. Div. 783, 176 N. Y. Supp. 378.

Violation of Law Voiding Accident Policy.—In an action on an accident policy payable on the insured's death from bodily injuries, directly and approximately the result of and caused solely by external, violent, and accidental means, it appeared that the deceased, having possession of a hypodermic needle in violation of New York Public Health Law, Art. 11A, directed his daughter to insert it in his arm, which resulted in blood poisoning, causing his death. The New York Appellate Division held that the complaint was properly dismissed, as the word "accidental" does not contemplate an insured's deliberate act constituting a crime. The suggestion that the insured did not know the law, and did not, therefore, intend to commit a crime, was held of no consequence.—Townsend v. Commercial Travelers, etc., Acc. Assn., 177 N. Y. Supp. 68.

THE KIDNEY AND PAROXYSMAL HEMOGLOBINURIA.

THERE seems to be a tendency to admit that the kidney is the elective agent for the destruction of the red blood corpuscles in paroxysmal hemoglobinuria, a certain number of clinical agreements pleading in favor of this theory, and in this respect the presence of casts and albumin is to be particularly mentioned. Not only does albumin accompany the excretion of hemoglobin, but it also precedes and continues after it, and in the aborted cases of hemoglobinuria it takes the place of the hemoglobin. This fact is all the more interesting in that an examination of the deposit after centrifugalization also reveals a cytolysis of the tubuli contorti, occasionally even the presence of pigment granules. Albuminuria, casts, the emission of pigment granules, as well as of methemoglobin and urobilin, to a certain extent might seem to indicate the active interference of the renal parenchyma. Besides these symptoms, the changes in the percentage of urea, the chlorides, and urates must be taken into account. According to some, all these signs indicate a latent nephritis which continues a quiet evolution in the intervals of the paroxysms. The uremigenic, hydropigenic, and albuminuric simple chronic nephritides offer a soil for the development and evolution of Harley's disease. And yet more: True attacks of acute nephritis, accompanied with massive albuminuria, may arise during the intervals of the paroxysms of hemoglobinuria and enough instances are now known to leave no doubt in this respect.

It is likely that the renal phenomena of hemoglobinuria are subordinated to a genuine renal congestion, itself provoked by spasm of the peripheral vessels as the result of cold. This congestion is accompanied by small glomerular hemorrhages, and secondarily the destruction of the extravasated red blood corpuscles would explain both their absence in the urine and the hemoglobinuria.

The mechanism of renal hemolysis is still under discussion, and various opinions are maintained. According to some, the destruction may take place in the urine, be it toxic or osmotic; others maintain that the destruction takes place in the renal parenchyma, whether an accumulation of carbonic acid gas is incriminated in an organ with a slowed circulation (Murri, Boas, Hijmans, van den Bergh), or, on the other hand, whether true hemolysins are present, their starting point being in the kidney itself. It is clear that the door is still open to hypotheses and it would be premature to pass judgment on any one of them, but nevertheless it may be assumed as very likely that the destruction of the red blood corpuscles is effected in the renal parenchyma and not in the grosser excretory tracts. That the renal theory of paroxysmal hemoglobinuria must not be regarded as exclusive is clear, because this conception alone would not explain the hematological data which we possess; and without reference to hypercholemia which occurs with the paroxysms, no one can reject the evidence of blood fragility and that of Donath and Landsteiner's test, which, regardless of their inconstancy, have been verified by a large number of competent observers.

A few years since, Gilbert and Chabrol proposed the splenohepatorenal theory of hemoglobinuria. By the splenic factor they were able to establish the synthesis of the various hematological manifestations observed—blood fragility or hemolysinemia; by the renal factor they explained the appearance of the hemoglobin in the urine. The kidney intervenes secondarily, either for eliminating the hemoglobin previously dissolved in excess in the blood serum or for completing a work of cell destruction begun by the hematopoietic organs. The red blood corpuscles rendered fragile by hemolysins derived from the spleen, undergo a complement of change in the renal parenchyma which ends in the liberation of their hemoglobin. This renal hemolysis is greatly aided by the action of cold which, by producing renal congestion, slows the circulation in the organ and brings about effraction of numerous glomerules, so that in certain paroxysms a minute hematuria may occur at the same time as a simple hemoglobinuria. Thus in a single theory can be reconciled the data furnished by a comparative examination of the blood and urine. The action of the spleen is indicated by blood fragility and Donath's test and if to this the renal element be added, the complex syndrome of paroxysmal hematuria will be found realized.

THE CHOREA OF CHILDHOOD.

CHOREA among children appears to be on the increase. If this is the case, it is not a matter for surprise when the exciting conditions of the past few years are taken into consideration. All nervous diseases have increased, and even if chorea is not strictly speaking a nervous affection, its most characteristic manifestations are nervous, and even if its origin is rheumatic it is likely that the toxemia or infection of rheumatism has been increased among the general population and the soldiers of the warring countries by the conditions under which they have lived of late. Sydenham's chorea or the ordinary chorea of childhood is described by Dr.

James Burnet in the *Prescriber* for October, 1919, as an acute disease which is practically always of rheumatic orgin. Recently it has been stated that it is a manifestation of syphilitic infection, but Burnet holds that this is a view which cannot be readily accepted. According to the late Sir W. H. Broadbent and his son, Sir John Broadbent, writing on the subject in "Quain's Dictionary of Medicine," 1902, so intimate is the connection between chorea and rheumatism that chorea must be looked upon as a manifestation of the rheumatic diathesis. Others have maintained that chorea is a purely functional affection, which may be compared with epilepsy. There seems to be little doubt, however, that the assertion that chorea is of rheumatic origin is based on the strongest evidence. Burnet acknowledges that all cases of chorea are not due to rheumatism, but his belief is that practically all owe their inception to a rheumatic tendency. He is opposed to the routine treatment of the condition which usually consists in keeping the patient in bed, and prescribing arsenic in increasing doses. He considers such rule-of-thumb treatment as highly unsatisfactory, and draws attention to the fact that chorea in itself is rarely dangerous, but its frequent association with serious heart mischief constitutes its gravity. Great stress is laid on rest and diet and details as to these are tabulated. The importance of massage is emphasized.

With regard to the best drug to be used Burnet is especially emphatic. As chorea, in his opinion, is practically always rheumatic in origin, the drug to be given is sodium salicylate. Personally he prefers acetyl-salicylic acid, which is more readily taken by children, as a rule. Such drugs must be given in large doses. Because of the tendency which the administration of sodium salicylate has to produce acidosis, it is generally advised that it should be given in combination with sodium bicarbonate, but Burnet thinks that if the alkali is given at all it should not be administered in combination with the salicylate. He is particularly opposed to the routine prescription of liquor arsenicalis. Large doses are necessary, and it is well to recollect that arsenic is a poison. Moreover, arsenic does not cure rheumatism, nor can it aid in warding off those heart complications so often seen in cases of chorea.

It is curious how views of treatment change. Arsenic has been considered and still is considered by many as almost a specific for chorea. In the article by the Broadbents it is stated that the drug that has been found most useful is arsenic given in doses of three minims of the liquor arsenicalis three times a day, and gradually increased up to ten or even fifteen minim doses. However, these writers do not appear to be convinced as to the efficacy of arsenic as in a later part of the same article they say: "It is doubtful if any drugs are of great service."

If chorea is, as Burnet insists, almost invariably of rheumatic origin, then it would seem that the rational treatment is by the remedy par excellence for rheumatism. And yet is it heresay to ask, are drugs of any particular service in the treatment of chorea? Rest and diet are essentials of treatment, according to Burnett, and it is likely that few will disagree with him. Also, there is no doubt that the advice is sound that throughout the course of the disease great attention should be paid to the stomach and bowels, and the simpler the remedies administered the less likely is the digestion to be upset.

RURAL MEDICINE.

THERE is no doubt that far more interest is taken now than ever before in the health of the people who live in the country. Rural medicine is being talked about, written about, and thought about; and it is high time. Two things need most to be done. First, modern medicine, with its accurate methods, must be made available to the rural population. Second, quacks and patent-medicine vendors must be eliminated from the villages and towns where they are still doing such flourishing business. Accomplishing the first should be a long step toward accomplishing the second.

The mobilization of our army, which showed to how great an extent our young men were (and are) still engaged in agricultural pursuits, showed also how ill-equipped our smaller communities are medically. This is no implication that the "country doctors" in the army were at all inferior to their metropolitan brethren, for the extent to which the city practitioners have allowed themselves to drift behind the times was and is truly phenomenal. The point is that neither the cities nor the villages have recovered from the flood of ill-trained doctors which the low-grade medical schools turned loose before they were obliged to close their doors. Many of these men would care little and know less about a blood culture or a phenolsulphonephthalein test, no matter whether their habitat were rural or urban.

Medical leadership has naturally concentrated in the cities, where both equipment and abundant clinical material are at hand. But that is no reason to scorn the country doctor, for it is the shortage of clinical material only that is responsible for the relative lack of modern medical methods in the smaller towns. There doctors are few, patients are scattered. One man must treat anything from pneumonia to fibroids. Such a man gets none of the benefits of stimulating contact with progressive colleagues. He has little incentive except to get through the day's work and try to collect his fees.

Recently, even within the last year or two, a change is apparent. The larger cities are now getting to be fairly well equipped with better-trained men, who can afford to specialize. Crowded conditions and high prices are turning more and more young men to the smaller communities. These men have seen large numbers of cases in the hospitals and dispensaries. They have had the value of careful laboratory work impressed upon them; *x*-rays,

Wassermann tests, have been easily obtainable. The result is that it is now by no means rare to see in our smaller towns a group of "moderns" bidding against the "old-timers" for popular favor. With many, a gray beard still goes further than a blood count. But thanks to the agricultural schools and to the army and to the automobile, the countryfolk are demanding modernism; and they will demand it in their medical treatment. The "old-timers" will either adjust themselves or find themselves with a waning clientèle.

The First Case of Encephalitis Lethargica in Switzerland.

Before the appearance of encephalitis lethargica in Switzerland the publication of cases by Economo, Netter, and Sainton had prepared the profession for its debut in that country. Nevertheless, when it did appear it was masked as tuberculous meningitis and only the autopsy made the real diagnosis. Technically the condition was acute primary polioencephalitis. Müller-Bergalone gives a very thorough account of the case in the *Correspondenz-Blatt für Schweizer Aerzte* for November 6, 1919, xlix, 45. It was necessary to exclude all other forms of encephalitis and there was little difficulty in ruling out the following: metastatic encephalitis from malignant endocarditis associated with embolism of cerebral arteries; metastatic encephalitis from some acute infectious disease, anthrax being thought of, in which capillary embolism from bacteria figure; encephalitis by direct propagation from some extracranial focus; encephalitis beginning as purulent meningitis; hemorrhagic encephalitis from thrombophlebitis, and grippal encephalitis. In every one of these encephalitides the process is a secondary one, the inflammation is of the polynuclear type and hemorrhagic in character, and there is no typical site. The process of exclusion does not end here. Chronic encephalitis of which the only known types are syphilitic or due to trypanosomes may be ruled out. There remains the polioencephalitic form of the Heine-Medin disease and here the parallel is quite close and only the immunity of the spine is left for exclusion. Lethargic encephalitis has spared the spine, but so far as the type of encephalitis is concerned it is the same in both conditions, even in the histological picture. Had there been infantile paralysis in the vicinity differentiation would have been impossible. On the other hand, clinically the meningeal component was pronounced. In the Heine-Medin disease the meninges participate and have even been alleged to be the starting point of the cerebral disease, but this participation is apparently more histological than clinical.

Sloughing Due to a Mustard Poultice.

The familiar mustard plaster or poultice is believed at the most to be a vesicant. It is conceivable, however, that under unusual circumstances a deeper or more intensive action might be forthcoming; for example, in a cachectic infant or on a paralyzed limb, but in practice there is little likelihood of the application of mustard under such circumstances. A case narrated by Jourdannet of Uriage in the *Journal de médecine et de chirurgie pratiques* for September 25 shows that accidents from this simple resource can occur if the conditions are favorable. The patient was a lad of 12 who was suffering from grippe with suggestion of pulmonary complication. The poultice was supposedly of flaxseed with mustard addition; it was applied over the back of the chest and left in place one hour (although the boy complained of the unpleasant sensation). When it was taken off, the skin showed a lively red and was dusted with talcum. It was not until a fortnight had elapsed that the boy, who complained of his back, was found to be suffering from multiple ulceration at the site of the poultice. There were several gangrenous areas which suppurated freely and were very painful. It was not easy to come by an account of the transaction, but so far as could be ascertained the application had actually consisted of pure mustard flour instead of flaxseed mixed with the irritant. Healing under soothing measures occurred very slowly, and once there was a reopening of some of the lesions. Three months were required for complete cicatrization. The entire experience was novel, especially the recrudescence of ulceration in the affected area.

News of the Week.

Antituberculosis Federation Proposed. — Antituberculosis societies of all the Allied countries will be asked to join in the conference to be held in Paris next October for the purpose of forming an antituberculosis federation. Preliminary arrangements for the conference were made at a meeting of representatives of American, British, and French societies held in Paris, November 14, and presided over by Leon Bourgeois.

Physicians and Pharmacists in Joint Session.— The annual joint session of the Medical Society of Charleston and the Pharmaceutical Association of the State of South Carolina was held in the assembly hall of the Medical College of South Carolina, November 17.

Priority in Medical Ideas and Discoveries.—At a meeting of the Section on Historical Medicine of the New York Academy of Medicine held on November 28, the principal subject under discussion was "the desirability of instituting a special medical board, which shall correspond to the patent office, the function of this medical board being to establish the priority of ideas relating to medical subjects."

Columbia University Plans Courses in Psychology as Applied to Medicine.—Several courses of lectures on psychology as applied to medicine have been instituted at Columbia University by the Students' Pre-Medical Association. The courses, each comprising six lectures, will deal with various phases of psychology which may be of use to the physician, and the manner of their application.

Influenza in Spain.—Recent dispatches from Madrid state that over 2,000 cases of influenza have occurred in the recent epidemic at Linares, about fifty miles northeast of Granada. The authorities have taken precautionary measures.

Vanderbilt University Medical Department to Be Reorganized.—The General Education Board, of which John D. Rockefeller is the founder, has appropriated $4,000,000 to Vanderbilt University, Nashville, Tenn., for the reorganization of its medical department along modern lines.

Venereal Disease Clinics.—The U. S. Public Health Service, cooperating with the State Board of Health, has established venereal disease clinics in Jacksonville, Key West, West Palm Beach, St. Augustine, Arcadia, Tampa, Pensacola, Hopkins, and Miami, Florida. The State Board of Health is inaugurating a statewide campaign of education concerning the necessity of guarding against the spread of venereal diseases.

Boston Surgeons Decorated by Prince of Wales.—Dr. Joel E. Goldthwait and Dr. Frederick A. Washburn were decorated by the Prince of Wales on his recent visit to this country, for the important services rendered overseas. Both were made Companions of the Order of St. Michael and St. George.

Johns Hopkins Building Burns.—McCoy Hall, one of the largest and most valuable of the old group of Johns Hopkins University buildings, was burned November 27. The property was valued at $50,000.

Antityphus Campaign in Siberia.—A resolution, recently transmitted through the Russian Embassy to President Wilson as president of the American Red Cross, expressed the gratitude of the people of north Russia and Siberia for the enlarged antityphus campaign which the Red Cross had recently undertaken. The Red Cross plans for fighting typhus, which spread alarmingly with the beginning of winter, included the doubling of its forces and facilities in Siberia. It has begun the construction of three great quarantine camps at Omsk, Ishim, and Petropavlovsk. Each of these camps will have a thousand beds, and ample delousing and disinfecting plants to take care of both soldiers and civilians. The construction is financed by the Omsk government, while the Red Cross will supply supervisory personnel and some of the medical and hospital supplies.

Bacteriological Laboratories Opened in Poland.—Diagnostic laboratories have been set up for refugee work at Pinsk, Lwow, Wladiwice, Wilno, Kielce, Lublin, and Minsk in Poland. Polish bacteriologists who, at the beginning of the war, were conscripted into military service by the nations to whom their particular parts of Poland happened to belong, and who for five years served their hated masters, may now work in the service of their own country, in these laboratories, equipped by the American Red Cross with such supplies as were not obtainable in Poland. The Polish government invited these men to the "reviewing school" at the University of Lwow, or Lemberg, in order that they might regain their former skill of eye and hand, and become familiar with all the advances made since the closing of their own laboratories. In the fight against typhus and other epidemic diseases which is now being carried on in Poland, the return of these bacteriologists is of the utmost importance.

Dr. Fred H. Albee, who has just returned from Europe, where he attended the Inter-Allied Congress at Paris and Rome, as official representative of the U. S. Army Medical Department, has been released from service, and has resumed practice at 40 East Forty-first Street, New York City.

Dr. Albert H. Garvin, for twelve years superintendent of the New York state hospital for incipient tuberculosis at Raybrook, has resigned this position to become associated with a similar institution located near Detroit, Mich. Dr. Garvin was graduated from Yale University School of Medicine in 1903.

Dr. W. Sohier Bryant has returned from service overseas and has resumed his practice at 107 East Thirty-ninth Street, New York City.

Dr. Jacob Sobel, of 140 West 122d Street, New York City, has been appointed Professor of Hygiene at the Fordham University School of Medicine.

Dr. John Van Doren Young has removed his office to 16 East Seventy-fourth Street.

Dr. Thomas F. Reilly was appointed visiting physician to St. Vincent's Hospital at a meeting of the medical board of the hospital, held November 11.

Philadelphia Medical Club.—At a reception held on October 17 William C. Sproul, Governor of the State of Pennsylvania, was the guest of honor, and J. Hampton Moore, Mayor-elect of the city of Philadelphia, made a speech.

Charitable Gifts.—By the will of the late George W. Elkins of Philadelphia the sum of $500,000 is bequeathed to the Hahnemann Hospital of Philadelphia and a like sum to the Abington Hospital.

By the will of the late Elizabeth E. Kilburn of Philadelphia the sum of $500 as well as a portion of the residuary estate are bequeathed to the Methodist Episcopal Hospital.

By the will of the late Kate E. Nessly of Torresdale, Philadelphia, the sum of $500 is bequeathed to the East Liverpool Hospital of East Liverpool, Ohio.

Mr. Charles M. Schwab has made a gift of $40,000 to St. Luke's Hospital, Bethlehem, Pa., to pay for the newly built Victory Ward. Mr. A. N. Cleaver had made a gift of $5,000 to the memorial fund in the names of James C. Haydon, one of the charter members of the Board of Trustees.

Obituary Notes.—Dr. A. F. Bock, of St. Louis, Mo., died November 14, at the age of 73. Dr. Bock, who was born in Waterloo, Ill., had practised in St. Louis for fifty years. He was graduated in medicine from the University of Würzburg, Germany, in 1868.

Dr. Eugene Jackson Smith, a graduate of Rush Medical College, Chicago, in 1872, died at his home in Harlan, Iowa, on October 24, aged 69 years.

Dr. Stewart Alfred McComber, associate director of athletics at the Foyer du Soldat, died of cerebrospinal meningitis at the American Hospital, at Neuilly, France, on November 5. He went overseas in a Y. M. C. A. contingent in July, 1918. He was graduated from the Detroit Medical College, in 1903, and was formerly physical director and professor of hygiene in Union College, Schenectady, N. Y.

Dr. Algernon S. Garnett, formerly of New York, the last surviving officer of the Confederate ram *Merrimac*, died at his home in Hot Springs, Ark., on October 30, aged 86 years.

Obituary.

ALLAN McLANE HAMILTON, M.D., LL.D.,

GREAT BARRINGTON, MASS.

Dr. ALLAN McLANE HAMILTON, alienist and neurologist, died suddenly, November 28, at his summer home at Great Barrington, Mass.

Dr. Hamilton, who was the grandson of Alexander Hamilton, was born in Brooklyn in 1848. He was graduated from the College of Physicians and Surgeons, New York City, in 1870. He was professor of mental diseases at Cornell University Medical Department from 1900 to 1903.

During the thirty-five years of his practice as alienist Dr. Hamilton was associated with more than a hundred murder trials, and with many other celebrated cases in which insanity played a part. He was called upon to testify in the trial of Guiteau, who shot President Garfield, and of Czolgosz, the assassin of President McKinley. Other trials in which he appeared were those of Carlyle W. Harris, Marie Barberi, and Harry K. Thaw. During the litigation in which Mrs. Mary Baker Eddy, head of the Christian Science Church, was involved, and in which Mrs. Eddy's sanity was called into question, Dr. Hamilton made a close study of her, declaring his belief in her sanity.

Dr. Hamilton was a member of the leading medical societies of this country and a Fellow of the Royal Society of Medicine of Edinburgh.

In addition to a long list of contributions of periodical medical literature, Dr. Hamilton was the author of "Nervous Diseases," "Medical Jurisprudence," "A System of Legal Medicine," "Intimate Life of Alexander Hamilton," and "Recollections of an Alienist." In 1913 he retired from active practice, devoting his time chiefly to writing.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, November 15, 1919.

Tuberculous Soldiers in Great Britain.—At the Tuberculosis Conference held recently in the Central Hall, Westminster, Lieutenant-Colonel Raw stated that he had succeeded in gaining the appointment of a committee to inquire into the cases of soldiers or sailors incapacitated by tuberculosis contracted in the service and to recommend the form that help should take. The committee found that 30,000 to 40,000 men were sufferers, and though much had been done the means of treatment were inadequate. It was hoped that a large number of extra beds would be forthcoming, as, from the beginning of the year, the Exchange had assumed what was in effect an unlimited liability in regard to the cost of treatment over the period considered necessary by competent medical opinion. The association of the sanatorium with the training colony in the permanent village settlement was the suggestion he made. At the training colony, gardening, farming, pig and poultry rearing, forestry, flower and fruit growing, etc., would be taught. The committee recommended the Government to appropriate £1,000,000 to the provision of permanent village settlements, and £250,000 for the immediate provision of training colonies. While the above were the views of the committee with respect to the treatment of the tuberculous, opinions of authorities in Great Britain vary to a very considerable extent on the subject. Many hold that the sanatorium is not of much use, others contend that when employed properly it is an important if not an essential factor in the treatment of pulmonary tuberculosis. As for village settlements, training colonies, and so on, there is no decided unanimity.

The First Woman's Hospital in Great Britain.—The name of Dr. Elizabeth Garret Anderson is a household word in Great Britain. She, more than any other woman, aided the cause of the medical education of women in this country, thereby elevating the status of the female medical graduate. Dr. Anderson was absolutely the pioneer of the entire movement for the medical education of women, and the Memorial Hospital in Euston Road, established to perpetuate her name, was the first women's hospital in London. During the few years of its existence it has amply justified its foundation. It is situated in a poor neighborhood and its services are always in demand. One test of a hospital's success is its waiting list, and this test applied to the Elizabeth Garrett Anderson Hospital is eminently conclusive. Its waiting list is always long. An endeavor is being made now to endow fifty beds at a thousand pounds each in order to place the coping stone on the project. Forty-five thousand pounds have been collected, so that it may be said that the object of the appeal has been practically realized. It is interesting to note that a bed was endowed in memory of Dr. Elizabeth Blackwell.

New Medical Appeal Board.—It has been announced recently that the Minister of Pensions has completed arrangements for the establishment of a Medical Appeal Board at each regional office. The board will deal with applications which are based on dissatisfaction with the assessment of disablement by a previous medical board. They will examine the appellant, and will have before them all the relevant documents, including those relatting to the proceedings of the previous medical board, along with medical information which the appellant himself may furnish. They will then be in a position to give an authoritative opinion. Their decision will be binding during the currency of the previous award, provided that the assessment may be reviewed during that period if the man claims that his condition has become substantially worse since the Board's decision. It will be open to the Medical Appeal Board to raise or lower an assessment, and in every case the appellant will be informed of the decision at the time of hearing. Notice of intention to appeal must be given in the first instance to the Local War Pensions Committee.

Ill Health of Pupils at Elementary Schools.—In this country, as no doubt elsewhere, there is a great deal of ill health among young children, and especially among those of the working classes. The war showed that a very considerable proportion of the young men examined for the army, if not actually unfit, suffered from more or less serious defects, bad teeth being the chief of these. Moreover, it was demonstrated that many of these defects were entirely preventable and that if they

had been treated in time, the young men of Great Britain would have been in a vastly better physical condition. An instructive commentary on this statement is supplied by the coming publication of the sixth volume of Sir Malcolm Morris's "English Public Health Series." The work in question is written by Dr. Joseph Cates, medical officer of health for St. Helens, and deals with "The Welfare of the School Child." St. Helens is a flourishing industrial center not far from Liverpool. The object of this little book is to convince the public of the alarming prevalence of ill health among pupils in elementary schools, 80 per cent. of whom suffer from bad teeth, 10 per cent. from malnutrition, and 20 per cent. from defects of the throat and nose due to adenoids and enlarged tonsils. According to the author these hindrances to a healthy education are largely due to the unsatisfactory housing of the masses. From time to time articles appear in the American and Canadian Medical journals of a like tenor. Bulletins of the Public Health Service within the past two or three years have dealt frequently with the conditions of ill health that prevail among American school children and perhaps among those of some of the Southern States in particular. This all seems to go to show that in the old world and the new, the future of medicine lies to a great extent in this department of prevention.

The Influenza Scare in Great Britain.—It is being freely predicted that there will be a recrudescence of influenza in this country during the winter. Perhaps the people who thus predict have grounds for their gloomy prognostications in reviewing the history of former epidemics and pandemics of the disease. It will be remembered that the pandemic which began in 1889 continued with remissions of at least three years. It is not unlikely then that influenza may be prevalent in the coming months. On the other hand, it is certainly not an act of wisdom to be constantly uttering prophecies calculated to arouse dread, as fear renders a person more susceptible to infection. Yet a certain amount of warning may do good, for it puts one on guard and impels one to take some essential precautions. It has been suggested in some lay papers here that medical men are responsible for the dissemination of statements with regard to the probability of influenza once more holding sway. If some doctors are unduly pessimistic, it is not the case with the majority, and the principal medical journals have strongly deprecated the spreading abroad of such prophecies of evil.

The Situation of the British Hospitals.—There is scarcely a hospital in Great Britain which is not more or less financially embarrassed, and many of them are pleading for funds in order to be able to "carry on." The condition of St. Bartholomew's Hospital, London, the most richly endowed institution of its kind in Great Britain, was referred to in a previous letter. An appeal is now being made for another important London hospital, the Middlesex, one which is probably as well known to visiting American medical men as any, chiefly because it is where Sir John Bland Sutton operates. The first social function which the Prince of Wales will fulfill on his return from America will be to preside at the Festival Dinner for the Middlesex Hospital which is to be held on December 9. The Prince made the engagement some time ago, desiring that his first appeal for the great cause of the hospitals should be for the Middlesex. Family feeling largely inspires this interest, for, while King Edward's Fund and the League of Mercy are witnesses to the personal care respectively of King Edward and King George for the voluntary hospitals, the Middlesex is that most intimately connected with Queen Mary. The brother of the Queen, the Earl of Athlone, formerly known as Prince Alexander of Teck, always took upon himself the task of looking after the welfare of the Middlesex Hospital as his special concern. The object of the dinner is to raise as much money as possible toward decreasing the debt of £200,000 which has been incurred in urgently needed restoration and enlargement. Of course, it is obvious that institutions mainly dependent on public and private charity for their support must, under the existing circumstances, be in a somewhat parlous way. During the war they were full to overflowing, expenses were more than doubled and the income was correspondingly decreased. As a matter of fact, it becomes more and more abundantly evident that some other system must be substituted for the voluntary system. Great Britain may well be proud of the history and traditions of her magnificent charitable hospitals, but times have changed, an era of general reconstruction is at hand, and the hospitals will share in the reconstruction.

Training Disabled Nurses. — The Women's Branch of the Training Department, Ministry of Labor, has been authorized to arrange for the training of disabled nurses. The persons eligible are nurses in receipt of a pension who, by reason of their disability incurred on military service, are prevented from following their former occupation. The department will arrange for a certificate in all cases to be obtained from the Ministry of Pensions medical officer as to the candidate's fitness for the new occupation in which training is proposed. The maximum period of training is to be twelve months, but in many cases the period will be less. The training allowance will be the difference between the pension actually in payment and the pension of the rate for the highest degree of disablement, and in addition the Ministry of Labor will undertake the payment of fees within certain well defined limits.

Disabled Men in Civil Service and Employment.—Sir Robert Horne, the Minister of Labor, states that in the civil departments of the government, other than industrial establishments, the number of disabled men employed at the end of March approximated closely 5 per cent. It is estimated that by the beginning of December this percentage will be over eight. The arrangements with regard to government industrial establishments have not yet been completed, but the information now available indicates that the number of disabled men employed is over 5 per cent. The Railway Executive Committee are prepared to do all they can to find work for disabled ex-service men. It is estimated that the railways are employing between 3 and 4 per cent. of disabled men, but the committee are unable at present to guarantee the employment of a definite percentage, owing to the

necessity for reabsorption of men returning to the forces.

The Fees of Medical Practitioners.—In several parts of Great Britain medical men are now charging higher fees. In Aberdeen borough and county and in some districts in Kincardineshire it has been resolved unanimously that a substantial increase in medical fees should be made, proportionate to the increased cost of living and working expenses, particularly those of transport. There is no reason why medical men, than whom none have felt the increased cost of living more acutely, should not charge more than in the days when living cost about one-half of what it costs at present. In the economic struggle which is now going on, the professional classes are faring worse than any other, and the future does not look too promising.

4. A Suggestion for the Improvement of Obstetrics.—Rushmore and Paine review the scheme for dealing with the problem of the obstetric poor, as outlined in the report of the Committee on Public Safety, Sub-committee on Pre-natal Care and Obstetrics, which was appointed in Boston, in the autumn of 1917, during the emergency of war-time conditions. The report, which was issued soon after the signing of the armistice, had removed the justification for its existence as an emergency war-time committee, suggests a method deemed more nearly adequate for dealing with the problem of the obstetric poor than any at present employed. The plan outlined in the report fulfils the following requirements, which are fundamental in any scheme, providing skilled supervision, flexible delivery service, adequate nursing, at a reasonable cost: (1) Skilled supervision throughout pregnancy, labor, and the puerperim. (2) A delivery service which is so flexible that the patient receives just the attention needed. In one case, a medical student, a nurse, a midwife, or a member of the family might safely supply that delivery service. In a sense, to employ a highly trained obstetrician would be inefficient. In another case, only the highly trained obstetrician can undertake the management. (3) The plan must include hospital facilities for some of the patients (approximately 5 per cent. of all cases), but preparation must be made to care for a large proportion of the cases in their homes, where for various reasons the larger number of deliveries will occur. (4) Further, the plan must provide adequate nursing throughout; this can scarcely be emphasized too much.

8. The Spasmophilic Child. J. Epstein.

8. The Spasmophilic Child.—J. Epstein holds that one of the most important inherited abnormalities of childhood is the convulsive or spasmodic diathesis. The spasmophilic child is apparently healthy, but has a tendency to local or general convulsive seizures. It is usually a disease of infancy and early childhood. There is no known basic organic lesion of the nervous system in spasmophilia. The spasms are either the result of a functional disorder of the nervous system itself or of some metabolic disturbance which keeps the nervous system in a state of hyperirritability or hypertonia. In the etiology of spasmophilia there are evidently three factors present: (1) A faulty nervous system which is readily susceptible to convulsive seizures; (2) a general systemic process which keeps the nervous system in a hypertonic state; (3) a reflex irritant which when added to the other factors upsets the neuromuscular structure. Clinically the spasmophilic manifestations may be divided into: (1) The spasmophilic state or the spasmophilic diathesis; (2) late, latent, or obscure spasmophilic disorders; (3) local or general spasmophilic convulsions. A child who has the spasmophilic diathesis shows an increase in all reflexes, is usually irritable, sleepless, restless, and bad tempered, and there is an overexcitability of the peripheral nerves to mechanical and electrical stimulation. The late, latent or obscure spasmophilic disorders are of great clinical importance, but are difficult to diagnose. Mild cases of laryngospasm and cardiac irregularity may be the result of a subacute spasmophilic disorder. Pylorospasm, periodical vomiting, spastic constipation, peristaltic unrest, and repeated attacks of abdominal colic of obscure etiology are occasionally due to vagotonic spasmophilia. Bronchial spasm or asthma may be the pulmonary expression of this diathesis. Persistent enuresis and vasomotor pallor have their origin in the spasmophilic tendency. The general or local spasmophilic convulsions may be manifested in general spasms or eclampsia infantum; in tetany or carpopedal spasms; or in laryngospasms or laryngismus stridulus. The obscure or latent spasmophilic disorders which are mostly characterized by spasms of the internal organs can be diagnosed only by a history of a spasmophilic diathesis, by the signs and symptoms of spasmophilic manifestations and by the exclusion of other pathological processes. General spasmophilic convulsions must be differentiated from convulsions due to epilepsy, cerebral inflammations, severe toxemias, and uremia. The prognosis is marked cases is very uncertain. The convulsions as a rule stop sooner or later, but the damage to the nervous system is done. The treatment consists in prevention, proper diet, and medication.

3. Fetal Death.—J. G. McQuarrie presents a report covering a series of 2,717 deliveries in the University of California Hospital, the series terminating, Dec. 31, 1918. Patients in 2,215 cases were delivered in the hospital, and in 502, at their homes. Reckoning from the period of possible viability (the thirtieth week) to twelve hours after delivery, there were 97 fetal deaths. So many factors play their part in causing the death of a child after the first twelve hours of life that it has been most difficult to assign correctly the part played by injury at birth. The writer, in consequence, restricted the limits as above indicated. Within these limitations, the fetal mortality was 3.6 per cent. In addition, there were found in this series twenty-two cases of fetal death occurring before the age of viability, namely, during the fifth and the sixth months, bringing

the total deaths up to 119, or 4.4 per cent. As there were two instances of the delivery of twins, there were only 117 mothers who lost their babies. Under the causes of death the following are discussed: Syphilis, 15 cases; unknown causes, 17 cases; birth trauma, 36 cases; toxemia, 9 cases; fetal abnormalities, 8; prematurity, 5 cases; placenta previa, 2 cases; various causes, 5 cases. Under miscellaneous causes are included the deaths under the age of viability. The relation of the age of the mothers to fetal death shows a remarkable lack of variation. The ages are arranged in groups of five years. The smaller percentage of fetal death when the mothers were under nineteen years and over thirty-five years, as shown in a table, probably does not indicate the lower incidence of death at these ages, but is a result of the smaller number of cases in these groupings of the series. Normal pelves were found in 98 cases. The following abnormal conditions of the pelvis were found in the series; generally contracted pelvis; simple flat pelvis; rachitic flat pelvis; rachitic transverse contracted pelvis; assimilation; funnel pelvis. The presentations of the fetus included left occipito-anterior, 39; breech, 29; right occipito-anterior, 17; right occipito-posterior, 11; occiput-anterior, 3; left occipito-posterior, 2; right occipito-transverse, 2; face, 2; transverse position, 2; Cesarean section (position not given), 7; no data, 5. Nearly all the unusual positions are represented in the series.

3. Notes on the Serum Treatment of Bacillary Dysentery, and on Dysentery Arthritis.—Bernard G. Klein had the opportunity, extending from September, 1917, to November, 1918, of observing and treating a large number of cases of dysentery and dysentery suspects at No. 25 Stationary Hospital, Rouen. After excluding all cases of (1) amebic dysentery; (2) acute enteritis or gastroenteritis—generally diagnosed as "diarrhea;" and (3) various intestinal disorders, collectively termed "colitis," there remained 973 cases which, on clinical or bacteriological grounds, or on both, were adjudged to be examples of bacillary dysentery. In 412 of these cases dysentery bacilli were recovered from the stools. In 561 no dysentery bacilli were found, but the illness was in every instance marked by sudden acute onset, typical dysenteric symptoms and stools, and the absence on careful examination of *Entamœba hystolytica*. The evidence of the character of the stools was deficient in fifty of the cases from which dysentery bacilli were isolated. In forty-four no description of the dejecta during the acute stage was recorded, while in six it was definitely stated that the stools were not dysenteric in appearance. The cases were classified, for convenience, as *mild*, *typical average*, *severe*, and *grave*. A complete record of fifty-one cases treated with anti-dysenteric serum is given in tabular form. From the study of these cases the following conclusions were drawn: (1) Anti-dysenteric serum should be given in large doses—about 60 to 100 c.cm. (2) It is best given intravenously. (3) It is most efficacious when given early in the disease. (4) From the point of view of serum treatment a severe case of bacillary dysentery may be considered in three stages: (*a*) From the onset of the illness to a period somewhere about the fifth to sixth days. During this stage anti-dysenteric serum (especially if given intravenously) has a most favorable effect, both as regards averting a fatal result and hastening recovery. A minority of cases fail to respond even to this early treatment. (*b*) An intermediate stage, from about the sixth to tenth day. A case having reached this stage is likely either to die or recover, irrespective of serum treatment. Nevertheless, the rate and completeness of recovery may be still affected by serum, especially if given in large doses, such as 100 c.cm. (*c*) A third stage—the stage of "dehydration and profound intoxication"—generally starting about the tenth day. During this phase of the disease serum treatment is practically useless. A minority of cases which have lasted to the tenth day or beyond it (without passing into the third stage) are still benefited by serum given in sufficient amount. In this series of 973 cases of bacillary dysentery, true dysentery arthritis occurred in eight instances. The findings in these cases are given in detail.

4. The Use of Anti-Dysentery Serum in the Treatment of Bacillary Dysentery.—W. E. Waller reports the findings in 608 cases of dysentery which passed through the wards of a stationary hospital in the forward area in Mesopotamia, during the period from March 31 to December 31, 1918. Of these 140 were proved to be amebic; of the remainder, 341 were either proved to be bacillary, or regarded as such on clinical grounds. The remaining 127 were mostly light and convalescent cases of a type too doubtful for special statistical purposes. It was found that in the cases treated early by serum, the acute stage was of shorter duration, the tendency to chronicity less, and convalescence more satisfactory than in cases treated by serum late in the course, or by alternative methods. The clinician must decide for himself at what stage of the disease the serum treatment loses its efficacy. From observations on cases in which acute symptoms had persisted even up to twenty-one days, the writer was of the opinion that improvement frequently started if serum was given where no appreciable improvement had followed simple dietetic treatment and saline purgation. This improvement was especially marked in pyrexial cases. Arthritis occurred in six (1.2 per cent.) of the series, and constituted the most distressing and intractable complication encountered.

2. The Advantages and Disadvantages of Gauze Packing in Abdominal Operations—A. Ernest Maylard bases the opinions expressed on the subject under discussion upon prolonged practical experience coupled with careful observation. The question of the use or non-use of gauze packing arises only in operations upon the abdomen where sepsis in some form is found to be present, by far the larger number involving inflammatory affections of the vermiform appendix and the female pelvic organs. One may fairly assume that the effects resulting from the use of antiseptic gauze packs in external wounds of the body similarly result when these same agents are used for intra-abdominal lesions. The gauze pack becomes freely saturated with the exudates poured out from the lining walls of the space which has lodged necrotic tissue or been the cavity from which pus has been evacuated; and the assumption is probably correct that the antiseptic agent within the gauze has a sufficiently sterilizing effect upon these exudates to prevent any further septic advance.

Again, it is probably correct to assume that this absorption, by admitting of direct contact of the gauze with the lining walls of the septic area, excites a normal reaction and reparative influence upon the surrounding parts, inducing the formation of healthy, healing granulation tissue. It would appear, therefore, that, so far as serving to check the advance of sepsis and to stimulate the formation of a healthy granulating

wound, packing with antiseptic gauze is distinctly advantageous. Thus, one may not unreasonably infer that the beneficial effects obtained in the use of gauze packing for external wounds would accrue equally in the case of similar lesions occurring within the abdomen. If no other considerations entered into the subject it might be justly concluded that packing with antiseptic gauze a septic intraabdominal wound was at least a reasonable, if not a generally advisable, line of treatment.

But whatever the analogy between septic processes taking place within and without the abdomen there is absolutely none between the parts involved. The peritoneal cavity, with its viscera, introduces an entirely new aspect. There is nothing comparable between these parts and the external soft tissues of the trunk and extremities. Inflammation of these latter may have some impairing results, but they will be nothing compared with what may accrue should the bowel or the peritoneum be involved in a septic process. The introduction of these important factors into the discussion raises the question of the possible disadvantages connected with the use of gauze packing in the treatment of intra-abdominal septic wounds. In discussing the disadvantages the writer cites three cases indicative of the danger of the intra-abdominal use of gauze packing. In one the packing left *in situ* for only half an hour caused an acutely injected condition of the surface, to which it had become intimately adherent, of the visceral peritoneum covering a loop of small intestine. The rose color and slightly roughened appearance of this area was in marked contrast to the smooth, glistening, grey serous tunic of the healthy neighboring coils of bowel. In another case the gauze packing which in some way had been allowed to slip unnoticed into the wound formed a plug which ulcerated its way through the parietes of the second part of the duodenum, and had been carried down by normal peristaltic action to the upper part of the jejunum, where, for some unaccountable reason, it had stuck, proving a source of obstruction, which was relieved, two weeks after the first, by a second operation. In the third case cited, a piece of gauze packing was allowed to slip into the abdomen. The patient made a good recovery, and about three months later passed the strip of gauze per rectum, as he learned from the patient's physician, two years later, when called to see the patient for acute intestinal obstruction. He considered it not unreasonable to assume that the adhesions that were then found, in the last case, upon operation, together with a constricting band, were the result of a chronic adhesive peritonitis set up by the presence of the gauze for some time free within the peritoneal cavity. These cases are not cited to illustrate the risks attendant upon the use of gauze for strictly operative purposes—risks which may be avoided, and which, when followed by untoward results, might justly be attributable to a certain amount of culpable neglect—but to support the deduction that the presence of gauze packing in contact with healthy bowel for any length of time may result in perforation of the visceral walls. Another disadvantage arising from the use of gauze packing is that if the packing be employed in septic cases without the adjunct of an efficient drainage tube, it may act as a dam to the escape of any discharge.

The possible and, indeed, probable, irritative effect of the packing upon neighboring coils of healthy bowel, leading to a low form of adhesive peritonitis, possibly resulting in intestinal obstruction, may be mentioned among the disadvantages. Another disadvantage is that whenever an opening is maintained through the parietal wound for any time—and the longer the time the more likely is the accident to happen—a weakened cicatrix is almost the inevitable precursor of a ventral hernia. Lastly, the withdrawal of a gauze pack is a very painful process. From the foregoing it would seem that the disadvantages so greatly outweigh the advantages that but one conclusion appears warranted—that gauze packing should be avoided except under definite and clear limitations. These limitations, Maylard says, are: the use of as small a piece of gauze as possible and for as short a time as possible, which equally connotes the avoidance of large packs retained for several days.

7. Gallstone Disease Complicating Pregnancy.

1. Paronychia.—Douglas H. Stewart states that the term "paronychia" is applied to such conditions as felon, panaris, whitlow, paronchia tendinosa, paronchia osseosa, etc. These are not different diseases, nor are they instances of infection by different germs, but they are well known streptococcus-staphylococcus mixtures attacking anatomical structures of different or various areas. In other words, it is not the invader, but it is the part invaded that gives rise to effects that are so different as to bear different names. As to the matter of treatment, any patient suffering from paronychia needs either mercury or iron, or both combined internally. Locally the writer uses an application of his own biniodide solution. This contains one grain of calomel in two ounces each of tincture of iodine, glycerin, and alcohol. When this application dries, which will be in a few minutes, then the infected part is bandaged in a salve containing equal parts of extract of belladonna and glyceritum acidi tannici. This is covered properly and the whole finger is splinted as though fractured, a wooden tongue depressor being employed for the purpose. The absolute rest conferred by the splint is invaluable as a measure in any sort of abortive treatment. It is remarkable how many paronychias can be arrested or made to stop by this simple treatment, but if there is any throbbing or any tension, the unfailing rule is to employ the usual surgical procedure of incision. There are several ways of performing this little operation of which two at least are good. One is to make a longitudinal gash parallel with the long axis of the part; the other is to make a single gash parallel with the short axis of the same part. Of course any such gash, made more or less accurately as to placement, could hardly be compared to a careful, rather slow dissection, carried clear to the bone or through the periosteum, if necessary, or even involving boring a hole straight through the bone for the purpose of draining the medullary cavity. If an anesthetist with nitrous oxygen is not available then the expedient known as nerve blocking is invaluable. One way of accomplishing this is to take two solutions, the first, one-half a grain of novocaine in a dram of boiled water; the second, two grains of quinine and urea hydrochloride in the same quantity of water. Two areas in the semblance of a ring ⅜ inch wide or more are painted around the finger, the first on uninflamed skin and the second one-half inch proximal to the first. Along the proximal margin the novocaine solution is introduced, keeping the circle as superficial as possible, and a second circle is then made along the distal portion of the ring, as deep as possible. Then using the quinine solution, the process is reversed, injecting the lower margin as deeply as possible and the distal margin superficially. When properly done this produces an almost complete anesthesia sufficient for any manipulation whatever. A small drop of phenol or a little frozen tissue at the site of the original introduction of the hypodermic needle will make the whole procedure painless. In one case in which it was determined after consultation that the thumb would have to be amputated, the bone was broken in several pieces, thus securing good drainage of the medullary canal, with the result that the thumb was not amputated and subsequently proved a very useful member.

5. Gaining and Losing Power.—C. L. Redfield says that we know that physical strength is built up by physical exercise. Such exercise is used for that purpose in connection with all athletic sports, and has been used by the trainers of race horses for centuries. It is impossible to make an athlete out of a man by simply feeding him, neither can we make a 2:10 trotter out of the best horse in the world by simply feeding him. The same thing is true of mental powers. A man can get in that condition in which

he can carry many things in his memory only by many years of mental activity. Physical strength declines or degenerates as a result of physical idleness, as is seen by the fact that a sedentary man loses the strength he had in his earlier and more active days. These things are well known and may be classified as positive knowledge. While we do not have direct positive knowledge that mental powers decline as the result of mental idleness, we have plenty of indirect evidence on the point. Do powers continue to increase indefinitely by continued exercise, and do they continue to degenerate indefinitely by continued idleness? To this question the writer replies that such development of powers by exercise, and such degeneration of powers by idleness, continue as long as activity or idleness continue up to some unknown point near the end of life. This fact not only has a bearing upon a person's efficiency as a member of society, but it affects his powers of resisting disease, and his longevity under normal conditions. It also affects the inherited ability of his offspring, their powers of fighting disease, and their longevity. Concrete evidence bearing on this matter is discussed. All plants raised for any considerable length of time by division, like tubers, bulbs, cuttings, buds, or grafts, gain the power to produce root abundantly, and at the same time they lose the power sooner or later to produce seeds. By continually exerting themselves along particular lines plants develop new powers along those lines, and by continued idleness along other lines they lose the powers they originally had. Acquirement comes as a direct result of exercising the powers in existence. There is no hocus pocus operating through the germ by which a son can be born more powerful than his father without anyone having done any work to acquire that power. The idea that improvement in the powers of living things can come by mutation is scientifically unsound. It involves a belief in either special creation or spontaneous generation.

3. Observations on Flying Sickness, With Special Reference to Its Diagnosis.—H. E. Munroe has correlated a part of our existing knowledge of the effects of motion in the air upon human beings, and records his personal observations upon the conditions known as the various types of flying sickness. After a careful examination of a large number of aviators actually engaged against the enemy at various altitudes, he concludes that youths do not stand the strain imposed upon them as well as the more matured. Twenty-three to twenty-eight would appear to be the best range of age. The neurasthenic and temperamentally unfit are readily recognized and the diagnosis should be correct in almost every instance. The opinion arrived at regarding the flying capabilties of the individual concerned should usually agree with that of his squadron commander, if the clinical methods described in this paper are accurately followed. In flying the greatest stress falls, first, on the cardio-respiratory system; second, on the nervous system; and, third, the muscular system. It is obvious that with increased altitude the blood is deprived of the necessary oxygen to carry on the body process, with the resulting accumulation of those substances which bring on intoxication. Dyspnea and Cheyne-Stokes breathing are therefore quite common. The effects of this intoxication are pronuonced on the nervous system. Marked impairment of judgment is frequently noticed, though the person is quite confident that his mind is absolutely clear; perception is affected, while sensation remains normal; headache, after landing, and insomnia frequently follows a period where the aviator is compelled to go day after day upon long shows. These symptoms are associated with other signs of exhaustion, such as altered blood pressure, disturbed vasomotor system, associated hemic murmurs, relative insufficiency tremors, and increased reflexes. The appearance of these symptoms, to which may be added muscular weakness, largely depend upon the kind and amount of work done in a given time. Repeated and prolonged exposure to altitudes of 18,000 feet, with short intervals between flights, produce continuous cumulative stress, to which the human organism is compelled to give way. The effect on the nervous system has been summarized by Lieutenant-Colonel Martin-Flack, when he states that, in addition to the physical strain incurred by the judgment displayed in a simple straightforward flight, there is added quick response to changing atmospheric conditions, such as "bumps." This strain is not all cerebral in nature; there is a constant instreaming of impulses to the cerebellum concerned in the process of equilibration; to the medulla oblongata in making adjustment of the respiratory and circulatory mechanisms; to the spinal cord for the coordination of the reflex movement in the static muscular work involved; and all this in a rarified air. Sickness at high altitudes may simply take the form of slight discomfort, as giddiness, dizziness or gasping for breath. Nausea and vomiting do not occur very frequently among experienced pilots. Vomiting is usually due to a dilemma from wrong impressions. It is also frequently associated with vertigo produced by a hypersensitive labyrinth and consequent reflex action. The writer describes the routine method of examination which they believe to be useful in the proper classification of patients. The flying history is of value. A mitral valvular lesion should not debar a man from flying if the heart muscle is in good condition, and no signs of enlargement exist, providing the airman passes the breathing and U-tube tests. A rapid pulse is frequent, and in those who are beginning to suffer from flying stress a low systolic blood pressure is the rule. An excellent pulse in an aviator is a small range between systolic and diastolic pressures, as, for example, 25, with a return to normal after exercise in fifteen seconds. Jugular engorgement, augmented by abdominal pressure, is an indication of splanchnic flooding and of cardio-vascular debility. In regard to blood changes it has been observed that the cellular elements have been increased at the expense of the plasma. In examining the respiratory system the usual clinical examination is made of the lungs. The vital capacity and the supplemental air are taken by meter. Aviators with a vital capacity below 3,000 c.c. could not be regarded as fit subjects for flying. The supplemental air should be about 1,500 c.c. In testing the aviator's ability to hold his breath sixty seconds is considered good; many hold it seventy seconds or more. Those who are unable to hold their breath for more than forty-five seconds are considered doubtful subjects for good flying. In making the expiratory test with the U-tube 80 mm. is considered the minimum of this test. Oxygen may be tested by the decompression chamber devised by Dr. Robertson of Chicago or by the more simple method of the Flack bag. The writer describes pointing, vertigo, and falling tests. In considering the treatment he advises placing the patient in an absorbing environment, free from flying associations, gradual exercise, walking, and golfing; later, riding and tennis may be indulged in. Symptoms, such as flushed face, multiple murmurs and rapid heart, insomnia, headache, and tremors, disappear quickly when a patient is given a thorough rest.

False Suicide.—It is seriously claimed by Carelli that not every man found hung by the neck was a would-be suicide. Not infrequently young men meet this death without the slightest apparent motive. It is generally known that suspension by the neck will cause erection of the penis and ejaculation; hence it may be possible that an unusual form of sexual perversion underlies these cases. Proof is lacking, but in some of these cases aside from absence of motive all of the collateral conditions show complete unpremeditation so that we have a right to invoke this possibility in the absence of any other.—*Il Policlinico.*

Society Reports.

THE AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-sixth Annual Meeting, Held at Atlantic City, June 14, 16 and 17, 1919.

THE PRESIDENT, DR. GUY HINSDALE OF HOT SPRINGS, VA., IN THE CHAIR.

President's Address.—The Sun, Health, and Heliotherapy.—Dr. GUY HINSDALE of Hot Springs, Va., delivered this address. He stated that the relation of the sun to human health and the vital functions was of such great importance that any phase of this subject was worthy of consideration. He referred to the vast amount of work being done by meteorologists and students of geophysics in measuring sun radiation and the so-called electromagnetic influences of the sun and moon in relation to conditions on the earth. The sun was an immense source of energy, but the gravitational, potential, thermal, optical, actinic, and magnetic effects were the only ones that had as yet been measured. There was no doubt but that the magnetic field of the earth's surface was affected by disturbances upon the sun; the electrical field in the earth's atmosphere was also affected, at least indirectly, by the radiation from the sun. The writer referred to many of these phenomena in detail, and concluded that they compelled one to take a very broad view of solar radiation and to give to the electric energy of the sun a wider scope than at first thought would seem appropriate. From a study of the phenomena of radiation and their relation to electromagnetic influences it seemed that heliotherapy might owe some measure of its efficiency to the electric energy of the sun. They all knew that disturbances of the nervous and mental equipoise were often traceable not only to social environment but to climatic conditions, and, in the belief of the ancients, and even of the present day, to lunar influences. That solar irritation had a considerable influence was undoubtedly true. There was at present a remarkable and growing interest in heliotherapy, and it had won a place in the treatment of tuberculosis of the bones and joints and of the lungs. There was a notable tendency to extend the use of this method to a large variety of surgical affections in the military hospitals. It was systematically employed in these affections at suitable stations in the Alps and on the French coast, both on the Mediterranean and Atlantic shores. It had been carried out with marked success in Hampshire, England, and in America some systematic experiments had been made. Among the earliest were those carried out by members of this association and recorded in its transactions. One of the most ardent exponents of heliotherapy was Rollier, who during the last sixteen years had treated about 2,000 patients, both children and adults, by graduated exposure to solar radiation at his institution at Leysin, Switzerland. Rollier claimed about 75 per cent. of cures, and his clinical reports, fortified with photographs taken on admission and discharge, fully corroborated his reports. After reviewing the work of Albert Robin with reference to the treatment of tuberculosis by radiation, the writer stated that in America there was every opportunity for practicing heliotherapy for tuberculosis, and in the wider field which included many chronic medical and surgical conditions not necessarily tuberculous. There were now in the military hospitals many cases of tuberculous disease of the bones and joints, and, in addition, there were the inevitable torpid wounds, fistulas, frost bite, "trench foot," and the effects of caustic gases, lately a part of military practice. Many of these sufferers were being sent to foreign resorts and institutions, where they were given the additional help afforded by heliotherapy. He strongly urged the establishment of true sun cures in the Rocky Mountain region, preferably in Colorado, New Mexico, Arizona, and California. Among the places in which heliotherapy had been attempted on this side of the Atlantic there was a wide difference in the amount and quality of sunshine, the *sine qua non* of successful treatment; nevertheless, it had been carried out in such diverse climates as at Sea Breeze Hospital, Long Island, Narragansett Bay, Rhode Island, and at Perrysville, near Buffalo; at Toronto, Canada, and at Lakeville, Mass. Success had attended the efforts of members of this association stationed in Colorado and southern California, where the hours of sunshine were most uniform and least liable to interrupt the cure. Since the introduction of the Rollier treatment in the J. N. Adam Memorial Hospital in January, 1913, to January, 1919, 312 cases of bone joint, joint and gland tuberculosis and tuberculous peritonitis had been treated, with 197 apparent recoveries; 55 arrested cases; 31 improved; 19 unimproved, and one death. Among this number there were nine nontuberculous cases. The average length of stay for all surgical cases was 8.4 months, while the average length of stay of those who were discharged as apparently recovered or arrested was 13.5 months. Of the patients who remained three months or longer 67 per cent. were discharged apparently recovered or arrested. The length of stay had an important bearing upon the results of this treatment in surgical tuberculosis. It could safely be said that every case of tuberculous peritonitis, unless complicated by advanced pulmonary tuberculosis, or fecal fistula, would recover under the Rollier treatment.

The Tuberculosis School for Patients and Observation Hospital.—Dr. JOSEPH PRATT of Boston read this paper, in which he reviewed the general plan of treatment of tuberculosis. He stated that he believed rest, and particularly rest in bed, was the chief factor in the relief of the disease. Failure to employ the rest treatment explained the lack of success experienced by many of the public sanitariums, nearly all dispensaries, and in private practice. The records of the Emanuel Church Tuberculosis Class, covering a period of thirteen years, proved that tuberculosis could be cured at home in a large percentage of cases if the patients followed the strict rest treatment. Patients were persuaded that the rest treatment offered them the best chance of recovery and followed it strictly at home, and as a result of days and nights spent in bed out of doors, experienced a rapid disappearance of symptoms and a gain in strength and well being. The plan proposed by the speaker sought to utilize the experience gained in the home treatment by applying it to the treatment of large numbers of consumptives. It might be called a tuberculosis school for patients, physicians, and nurses. The plan had been worked out in some detail for the State of Massachusetts, but it could be applied to any other state or county, if money was available, because it could cooperate with existing sanatoria, or tuberculosis hospitals, or be used independently in places where such institutions did not exist. Essentially it was a school of home treatment. The ideal observation hospital would be an institution for twenty cases with all single rooms. There would be covered porches where the beds could be placed both night and day. There would be a well-equipped roentgenogram department under the direction of an expert, and a laboratory where research work could be done as well as the routine examinations made. The institution would be under the direction of the Commissioner of Health of the State. The chief physician would be a man selected for his experience both in the diagnosis and treatment of tuberculosis. He should be a man who would devote at least one-half of his time to the work and the salary should be sufficient to secure the services of the right kind of a man.

The Treatment of Tuberculosis in an Army Hospital.—Col. HENRY W. HOAGLAND of Colorado Springs presented this paper, in which he related his experience in the organization of army hospitals for the treatment of tuberculosis. He said that the first hospital he organized was U. S. G. H. No. 17, at Markleton, and the second U. S. G. H. No. 19, at Otine, N. C. In the organization and administration of an army hospital a system had to be found which would insure that among an average of 1,500 patients not a single soldier should fail to receive the daily personal care of a medical officer, for this was more important in tuberculosis than in almost any other disease. In order to attain this end the hospital was divided into six separate units, namely, the receiving, the infirmary, and four ambulatory wards. Over each of these groups

was placed an officer and under him was an officer for each individual ward. The officer in charge of individual groups was held responsible for the care of the wards under him, and was also responsible to the chief of medical service. All patients were classified as to the extent of their lesions, the classification varying with the progress of the case. The groups were designated A, B, C, and D. A system of rotation was followed. The patients were admitted to the receiving wards, where the history, clinical findings, *x*-ray, and sputum and urine examinations were made. The men were given short talks on the nature of tuberculosis, its treatment and cure, and the patients were then classified. If an active case was received he was sent to the infirmary wards, "D." When a man had progressed sufficiently he was sent from the infirmary to an ambulatory ward corresponding to the grade to which he had progressed. Finally, when a man had progressed to Class A, or became an arrested case, he was sent to the wards in which he was fitted to be returned to active duty, or after the Armistice was signed, to civil life. A reconstruction department was established, and no single agency ever changed the morale of an institution as this department. There was an almost immediate improvement in the attitude of the patients. They found that they could not only regain their health, but that they could educate themselves to be more useful, not only to their country but to themselves. An illiterate could learn to read and write, and much special knowledge of a practical nature could be acquired. Since many of these occupations meant exercise the entire medical staff were instructed that, while exercise was one of the most dangerous remedies, it was also one of the best aids in the treatment of tuberculosis, but it had to be prescribed as one would prescribe morphine, cocaine, or strychnine. The ward surgeon, the man who came in daily contact with the patient, was made responsible for the prescribing of work or exercise. The patient was sent to the reconstruction department with a prescription that he could do a certain kind of work for a certain length of time, his preference for the kind of work having been consulted. His pulse, temperature, and respiration were taken half an hour after his return to the ward, and his general symptoms were noted. Upon this daily record depended the increase or decrease of the exercise. The subject of recreation was also given considerable thought. It was believed that by careful attention tuberculosis could be arrested more quickly by the judicious use of graduated exercise, and also that a fair amount of the cure was psychological. Such matters as fresh air, rest, and balanced ration were of course included in the treatment. The use of tobacco, while not denied, was restricted. The one thought was to regulate every hour of the day so that the patient could live a life that enabled him to get well and made time pass quickly for him. The experience of the year as the commanding officer of two army hospitals made the speaker believe that several points could be of great value: (1) A large number of men suffering from tuberculosis could be treated at one institution conducted by a proper system. (2) Exercise properly prescribed was a valuable remedy. (3) A reconstruction department could be established for the treatment of tuberculosis.

The Army Tuberculosis Problem as Seen in Massachusetts.—Dr. JOHN B. HAWES of Boston read this paper, in which he stated that up to May, 1919, there were 1566 Massachusetts men who had, during the years 1917, 1918, and part of 1919, either been rejected by the draft or discharged from the various camps on account of tuberculosis. Detailed information regarding these men had been obtained through local boards of health. Many of these men were known to be tuberculous, and their rejection by the draft boards was a matter of form only. A considerable number, however, were new cases. There were 491 definitely stamped by the draft boards as tuberculosis, the remainder being classified as suspicious. Of these 1566 men there were 548 in regard to whom the local authorities could give no information, 110 had died, and 500 were working and in apparently good condition. The speaker had been able to discover only 42 Massachusetts men who had been discharged from the service on account of tuberculosis; of these 29 were under supervision at home or in private sanatoria, and 11 were in state sanatoria. The real problem that the war had given them so far as tuberculosis was concerned was not the looking up of cases that had been classified as disappeared, or removed, or unknown, and it was not the collecting of information as to the facilities available for tuberculosis patients, but it was finding out how many of these men, discharged from the army or rejected in the draft on account of tuberculosis, really had that disease. Of greater importance still was the formulation of standards so that there would be in the future a clear and definite understanding as to what constituted active pulmonary tuberculosis from the point of view of the state board of health. From the point of view of a health officer Massachusetts had no tuberculosis problem as far as handling and disposing of the individual cases was concerned. He felt, however, that war had emphasized the problem which had previously existed as to how best to come to some practical and sane conclusion in regard to tuberculosis, its diagnosis, and treatment, and to formulate definite standards concerning it.

Dilatation of the Bronchi.—Dr. JABEZ H. ELLIOTT, Lieut.-Col. C. A. M. C., Toronto, Canada, read this paper, which was a review of 40 cases observed June, 1918-June, 1919. The disease was frequently confounded with tubercle of the lung and chronic bronchitis. It was not a rare disease, and its presence was frequently overlooked. Most of the cases were returned soldiers paraded for recommendation as to disposal. The remainder were cases seen at the special chest clinics at St. Michael's Hospital and the Hospital for Sick Children, with five from other sources. The disease was usually secondary to disease of the bronchial wall, lung, or pleura. In gas poisoning, bronchiectasis occasionally resulted, doubtless from the damage done to the bronchi, and aided by a degree of pulmonary fibrosis which followed the purulent bronchopneumonia or bronchiolitis which was not infrequent after chlorine and mustard gas. Diagnosis was summarized thus: For the diagnosis of bronchiectasis was required (1) evidence of the existence of a cavity, and (2) reasons for believing that the cavity was a dilated bronchus. The first might be a matter of fact, the second of opinion, and thus the diagnosis of bronchiectasis must in the nature of things be nearly always uncertain and often impossible. The conclusions based on the study of the 40 cases were: Bronchiectasis was not a rare condition, and would be frequently met with in a special chest clinic. It was to be differentiated in its early stages from bronchitis and tubercle of the lung, and in its advanced stages from pulmonary abscess and tuberculous cavity. Hemorrhage was frequent and might be slight or severe. Repeated examinations of the sputum for tubercle bacilli should be undertaken. Given purulent sputum which on a series of examinations showed no acid fast bacilli, the diagnosis of tubercle of lung was not justifiable until other chronic respiratory diseases had been excluded. Clubbing of the fingers and toes was a very suggestive symptom. In differential diagnosis a careful clinical history and a study of the symptoms and physical signs would usually determine opinion but the stereoroentgenogram was invaluable. Nutrition had been good in most of the cases, and this was of some assistance in differentiating from tuberculosis. So far as the *x*-ray findings were concerned, the single plate was of value only in the diagnosis of dilatations of the main bronchi or their primary divisions, not always being satisfactory here. For dilatation of the smaller divisions or in the presence of much peribronchial infiltration and pulmonary fibrosis the stereoroentgenogram was necessary. It was an invaluable aid in diagnosis.

An Analysis of the Examination of Over 100,000 Men Examined at Camp Lewis, Washington, by the Tuberculosis Board, and of 25,000 Soldiers Discharged from the Service.—Major RALPH C. WATSON of Portland, Ore., made this presentation, which consisted of a lantern slide exhibit showing tabulated results of these examinations and giving a graphic demonstration of the methods used. He stated that their work had been somewhat different from that done in other

camps. The effort was made to get men specially trained in tuberculosis work and to make the work something of model for work of this kind in army hospitals. The men to be examined were brought in in groups of twenty-five, and this was continued throughout the day, as many as 1,500 men being examined daily, while as many as 2,000 could be handled with the aid of a few additional examiners. The plan used for demobilization included the general examination, orthopedic, postural, eyes, ears, nose, and throat, and a dental examination, after which they were sent in for an examination for tuberculosis. Dr. Bushnell's outline was followed in this. All cases that showed any family history of tuberculosis, or those who had had pneumonia, typhoid fever, had expectorated blood, or were troubled with asthenia, or certain types of chest deformities, were passed on for a fluoroscopic and *x*-ray examination. They had been examining some 15,000 or 16,000 men per month in the course of demobilization.

The Diagnosis of Empyema.—Dr. J. N. HALL of Denver presented this communication. He said that the concentration in camps of many men, more especially young men from rural districts, gave opportunity for the wide diffusion of acute respiratory infections, and at the same time for an increase in virulence of the causative organisms. The pneumonias and bronchopneumonias departed very widely for the usual types seen in times of peace. The influenza epidemic added still further to the confusion, and during this period many purulent effusions occurred as accompaniments rather than as sequelæ of the pulmonary consolidation. The solidified lung, often held by pleural adhesions, could neither collapse nor retreat before the effusion, and it spread as a thin layer around the periphery of the lung instead of accumulating within the pleural cavity. Unless the absence of vocal fremitus was noted the effusion frequently remained unsuspected. Even if suspected, aspiration often failed to establish the presence of fluid, for the layer of fluid was often so thin that the needle passed through it, yielding only a dry tap. The only sure method was to insert the needle slowly, and the few drops picked up established the diagnosis microscopically. Another source of error lay in the presence of loculated, multiple effusions. One would frequently find as many as four pockets of fluid in the chest. There was no safety without the use of the needle in every suspicious area. Dr. Hall also called attention to a curious type of empyema in which the diagnosis often failed without the help of the roentgen ray, and sometimes with it. In these cases the effusion gathered above the arch of the diaphragm without coming into contact with the periphery of the chest at any point. The abscess finally broke through a bronchus, temporary recovery ensued. After describing a number of conditions in which empyema might remain undiagnosed, Dr. Hall emphasized the point that many empyemas were missed by not inserting the needle deep enough, and that the technique of using the needle was of great importance. The fact that only impaired resonance was present in the effusions in the upper fissure of the right lung should not be a deterrent to the use of the needle. If fluid was found in more than perhaps a third or a quarter of the taps made the needle was not being used often enough. In one of the speaker's cases which had been repeatedly and unsuccessfully aspirated the empyema was found on the thirteenth puncture and the patient restored to health.

The End Results of Employment of Ex-Patients in Sanatoria for Tuberculosis.—Dr. HARRY E. BARNES of Wallum Lake, R. I., read this paper, the object of which was to show the results of employing discharged patients in the sanatorium itself. He stated that the material upon which this article was based was obtained from the subsequent histories of 286 patients who were employed in the State Sanatorium at Wallum Lake, R. I., during the years 1906 to 1919, inclusive. The plan was that patients, before discharge, whose disease was undergoing arrest, were put on graduated exercise and work gradually increasing to a maximum of four and one-half hours' work daily. In most cases this work was more or less similar to the work later given them as employees. After employment the daily hours of work were eight for domestics, eight and one-half for nurses, and outside laborers, nine. Comparatively few, less than 10 per cent. of their patients, were considered fit to do work requiring heavy lifting. From the standpoint of the institution, the chief disadvantage of employing patients was the danger of relapse. The number of patients who relapsed during the time of their first employment at the sanatorium was 21 per cent. While it was a disadvantage to have employees 21 per cent. of whom would relapse with tuberculosis, this was more than counterbalanced by the advantages of knowing the character and ability of employees before hiring them and by the opportunity of quickly filling vacancies from the resident population. They were employing ex-patients as waiters, nurses, outside workers, housework (mainly cleaning), orderlies, laundry workers, assistant carpenters, and in miscellaneous positions. The end results of all patients employed were classified and tabulated by years. It was shown that about 69 per cent. of the patients employed by them were known to be living, while 521, or only 55 per cent., of similar groups not employed by them, were known to be living. Even though the employment in sanatoria did not prolong the life of the patients, it would yet be wise to give them preference in employment in order that money provided for fighting tuberculosis might so far as possible go to those who had suffered from the disease. When it could be shown that it did prolong life, it was even more incumbent on institutions for tuberculosis to employ expatients. The advantages of an employment bureau for tuberculosis patients fit to work, conducted by the National Tuberculosis Association or some other charitable organization were obvious. The writer concluded that patients ought to obtain work in sanatoria, if possible, as it increased their chance of survival about 25 per cent. Sanatoria ought to employ patients whose disease has become arrested or quiescent in preference to healthy persons, as it increased the number saved. There should be an employment bureau for finding positions for ex-patients in sanatoria.

Dr. E. O. OTIS of Boston stated that his experience had been limited as regarded the employment of tuberculous patients. He felt that this would always be a difficult problem because when a man was considered able to work he wanted to return to his former occupation and, as a rule, that was the best thing for him. Undoubtedly in a certain number of cases it would be beneficial to employ them in a tuberculosis institution, but at the present time the atmosphere of a tuberculosis institution was apt to cling about a man, and the sooner he could get away from it the better, provided his condition warranted his return to his former home. In the majority of cases he felt that the patient should go out and resume his former occupation.

Dr. CHARLES H. MINER of Asheville, N. C., stated that the work of Col. Hoagland and Col. Bushnell in the army was both surprising and pleasing, as well as encouraging. He had watched this work very closely and thought the first great difficulty in the army was the impossibility of getting a permanent personnel in the hospitals. The work of the army could not be standardized until they got men who were going to stay in the army. In the long run he felt that the problem would not be satisfactorily solved until the cooperation of specialists in tuberculosis was evoked. Another difficulty, and one that might be overcome was that the difference in grade of army officers made it difficult for them to get together. Still another great difficulty was that there was not adequate opportunity to carry on outdoor treatment. There were not sufficient outdoor accommodations for the men. There should be pavilions for fifty men each, where plenty of recreational advantages were afforded, and an ésprit de corps should be cultivated. The tuberculosis work in the army tuberculosis hospitals was admirable, and there was no reason why it should not be of value in advancing their knowledge of tuberculosis.

Col. GEORGE E. BUSHNELL of Washington, D. C., said that Col. Hoagland's work was very interesting, and served as an example of tuberculosis work in the army. The work had been handicapped by a lack of

medical officers, but he considered that Colonel Hoagland had made a success of it. Where so many men were to be handled it was better to divide the work into sections and to make each officer responsible for his section. He thought it possible for one man to handle 250 or 300 men, but more than that would be too many for one man to discipline. Dr. Bushnell said he considered the work done at Otine very important, because it demonstrated that it was possible to conduct a large institution for that class of patient with a properly selected corps of officers and assistants.

Capt. JOHN D. THOMAS spoke of two phases of Colonel Hoagland's paper that were important in his estimation, the psychological aspect of the work and the vocational reeducation or rehabilitation. He believed Dr. Hoagland's work would give them something to go on and he hoped that when men were sent out from the tuberculosis hospitals they would serve as examples of what vocational training could do for this class of patients.

Dr. FRANCIS M. POTTENGER of Monrovia discussed Dr. Pratt's paper. He said that in listening to this paper it had occurred to him that the important point was the training of assistants and attendants. It was not sufficiently appreciated that tuberculosis was difficult to handle. The cure of tuberculosis took rest and rest seemed such a simple thing that it was overlooked, yet it was the most important therapeutic measure. The psychological factor was another important thing. The patients had to go to these institutions against their will, and they would like to have it through with and get home again. The way to handle them was as had been outlined, that was by close association and approaching them in a simple way. They must also be taught that the institution was giving them the best opportunity in the world to get well. As to what should be done with patients after their discharge, Dr. Pottenger said he had been in the habit of telling patients that if the work was not too difficult they should follow their previous occupations, but to live right the rest of the time. So much strength and effort was required to enable a patient to adapt himself to a new field of work that it seemed that if his former occupation was not entirely too unsuitable he was better off in that. If he undertook a new line of work and failed it usually put the patient in a much worse condition than though he had gone back to his former occupation and regulated his life in accordance with what he had been taught while being under treatment.

Dr. JAMES ALEXANDER MILLER of New York expressed his admiration of the work that had been done in the army in regard to tuberculosis under the direction of Colonel Bushnell and Colonel Hoagland. He said we might not have had a war tuberculosis problem but we had a peace tuberculosis problem, and what had been done in the war would stimulate the peace program. He was particularly interested in Colonel Elliott's paper, because in New York, where they were examining many in whom there was presumptive evidence of tuberculosis they had found that 25 per cent. were nontuberculous. They found that a large percentage of these were cases of bronchiectasis, and many had localized pus in different situations, and were sent in with the diagnosis of tuberculosis. The value of the *x*-ray and the fluoroscope in differentiating these conditions should be emphasized.

Dr. JAMES M. ANDERS of Philadelphia said that speaking of the physical diagnosis of encapsulated pus in the pleural sac he had learned that certain rather definite physical signs were present. One must make a systematic physical examination, searching for areas of limited expansion, spots of defective resonance, and localized pleural signs. Another point to be emphasized was the advisability of making repeated exploratory punctures, very many if one felt convinced that a focus of infection was present.

Dr. J. N. HALL of Denver said that many doctors did not realize that following the epidemic of influenza one must expect to find a great wave of bronchiectasis. Many doctors thought that when empyema was present they ought to get pus every time they punctured. The needle should be used oftener. It was safe to say that even in the presence of an empyema one got two negative punctures for every positive puncture.

Major WILLIAM L. DUNN of Asheville, N. C., stated that in his opinion three or four things stood out particularly in the papers of the morning. The first of these was that the importance of rest in tuberculosis must be impressed not only on their own minds, but on the minds of the general practitioners, and also the fact that the period of rest was comparatively safe while the change from rest to exercise was the dangerous period. The hardening of the patient after the rest cure was very important, and should be done with care. Another point was the importance of some standard for boards of health by which they might determine what constituted clinical tuberculosis. Still another point that had been brought out particularly by the experience of the war was the way in which arrested cases withstood the test of war. This had forced him to change his opinion. He had been of the opinion that none of these cases should be admitted to the army. Colonel Bushnell's faith, however, had been justified. It seemed that some of the others who had been in tuberculosis work should have had the same faith as he had had.

Colonel HOAGLAND, in closing, said that the training of the medical officers of the regular army for tuberculosis work was very important, and the personal relationship between the doctor and the patient was also very important. There were very few instances where an officer was called on to care for more than 32 patients, and if a man could not handle 32 patients and keep in personal touch with them he was not a good doctor. The pavilion idea advocated by Dr. Miner was very good, but how to get the pavilions was another matter. The tuberculosis patient in an army hospital occupied an anomalous position. In civil life a man with tuberculosis wanted treatment, but the young men in the army did not want to remain there; they wanted to get out and go home, and that was why the reconstruction department had been such a great boon to these men.

Observations on the Epidemic of Influenza Occurring in the United States Naval Hospital in Philadelphia in 1918.—Dr. JUDSON DALAND, Lieutenant-Commander, M.C., U.S.N.R.F., Medical Consultant to the Fourth Naval District, Philadelphia, read this paper, which was based upon a study of the more serious of about 3000 cases of influenza occurring among the officers and men in the U. S. Navy in Philadelphia. Most of the patients were between the ages of twenty and twenty-six years, and were in unusually good physical condition. The general conclusions based upon this study were as follows: The epidemic was introduced into the United States by ships from abroad and differed markedly from preceding epidemics, being characterized by rapid and severe onset, extreme contagiousness, and high death rate. The period of incubation was from one to four days. The epidemic disappeared because most of the nonimmune had been infected. There was extreme susceptibility in the young adults and comparative insusceptibility of those past middle age. There was nonresistance to the disease, even by those of unusual strength and vigor. Toxemia was the dominant cause of symptoms, complications, and death, and it acted upon the tissues and organs of the body. Cyanosis occurred frequently, and if extensive was prognostically serious. The chief and perhaps the sole underlying cause of the cyanosis was toxemia. Some of the secondary causes of cyanosis were disturbance of the vasomotor system, toxic myocarditis, bronchopneumonia, and congestion, over full venous system, epinephritis, and suboxidation of the blood. Hypoadrenalism was suggested because of the frequency of low systolic and diastolic and large pulse pressures with adynamia. In a series of thirty-seven autopsies many showed marked disease of the adrenals. The importance of an exhaustive study of the adrenals was emphasized in future epidemics of influenza. The adynamia was probably due to the effects of the toxemia upon the nervous and muscular systems and the adrenals. Toxemia affecting the muscles and nerves connected with respiration probably caused the deficient pulmonary expansion. The most common location of a beginning bronchopneumonia was in the apex of the spinal half of the lower lobe of the lung. The bronchopneumonia might exist in the absence of breath sounds due to nonentrance of air and percussion resonance

might be normal due to an associated emphysema. The appearance of the streptococcus homolyticus in the sputum in influenzal bronchopneumonia was usually followed by death. Absence of compensatory over action of the normal lung when massive bronchopneumonia existed was an indication of a disturbance of the neuromuscular mechanism due to toxemia. Pleural friction frequently closely simulated the crepitant and subcrepitant râles of bronchopneumonia. Empyema was infrequent during this epidemic. Referred pleuritic pain was often mistaken for cholecystitis, or appendicitis. Feeble or absent apex beat, weakened muscular element of the first sound, and relatively slow pulse as compared with the temperature, were evidences of myocardial change or toxic myocarditis. There was frequency of toxic myocarditis at autopsy, as observed by the influenza committee of the Advisory Board, D.S.M.S., France. Meningismus was frequently mistaken for meningitis. The prognosis was usually favorable in post influenzal delirium and delusional insanity. The prognosis was unfavorable when vomiting was persistent. About three-fourths of the cases of severe toxic influenza developed catarrhal nephritis. Leukopenia was diagnostic of uncomplicated influenza. Polymorphonuclear leucocytosis was diagnostic of bronchopneumonia, and might antedate the clinical diagnosis by two or more days. The prognosis was unfavorable when influenza occurred in a pneumococcus, streptococcus, staphylococcus, meningococcus, tuberculosis, or typhoid carrier. It was probable that this epidemic had created a large number of influenza carriers. The sputum of 36 per cent. of patients convalescent for two or three weeks contained the *Bacillus influenzæ*. The influenza bacillus alone, or combined with other organisms, occurred in 62 per cent. of the sputa examined. There was frequent occurrence of pure culture of the *Bacillus influenzæ* from the diagnostic puncture of the bronchopneumonic areas of the lung. Type I pneumococcus was rare. There was a symbiotic relationship of the *Bacillus influenzæ* to the streptococcus or pneumococcus, and perhaps other microorganisms. Spirillae were frequently observed in influenzal bronchopneumonia, especially when the sputum was bloody. This epidemic of influenza seemed to have been primarily due to the *Bacillus influenzæ* which might have been of the pandemic strain possessing unusual virulency. This influenza bacillus not only lessened remarkably the resistance, but also greatly increased the susceptibility of patients with influenza to infection by other microorganisms. Many patients with influenza were quickly invaded by varying strains of the pneumococcus and streptococcus of high virulency. When an infection of two or more microorganisms occurred it seemed as though each stimulated the other to more rapid growth and greater virulency. Perhaps the symbiotic relationship of the influenza bacillus to the pneumococcus or streptococcus seen in the laboratory might also occur in the human laboratory. Spirilla so frequently observed in this epidemic might possess an importance now unrecognized.

Personal Hygiene in the Prevention of Influenza and Other Infectious Diseases.—Major THOMAS DARLINGTON, U. S. Army, of New York made this presentation. He stated that from what he had seen of the lack of personal hygiene in the army he felt that it was necessary to call attention to the need of teaching more personal hygiene which he was sure would be a great factor in preventing epidemics such as the recent epidemic of influenza. The prevention of infection might be considered from three standpoints: First, what persons could do for themselves; second, what people could have done for them, and, third, what could be done by the enforcing of national, state, and municipal laws with reference to public health. Under the first of these were all these things which were matters of personal responsibility, such as the regulation of ventilation, washing of the hands, the wearing of properly fitting shoes, the right kind and amount of clothing, the care of the eyes, nose, and teeth, and the cultivation of cheerfulness. Attention should also be given to securing a proper amount of recreation. In 1890 the epidemic of influenza traveled from east to west, and as it progressed it became more severe, many dying in from twelve to twenty-four hours of lobar pneumonia. Indeed, it was like the pneumonic plague. Many persons were easily fatigued because they did not drink enough water. Owing to a lack of water the system did not excrete waste products as it should, and phenol and indican accumulated, causing fatigue. Fatigue, in turn, reduced resistance. People made their own immunity. People did not know this, and did not know how to take care of themselves. Some might think that it was unnecessary to talk about washing the hands, but as a matter of fact the public were in need of education on this very ordinary matter of personal hygiene. Indeed, it was not so many years since even the physician failed to understand the importance of keeping his hands clean. In the memory of many of them the time was when a physician attended a confinement and delivered a woman without washing his hands. Another point was that if more tooth brushes were used there would be fewer cases of pneumonia. Keeping cheerful was a very important factor in the promotion of good health; physicians must teach the gospel of cheerfulness. It was a well-known fact that the condition of the adrenals depended upon the mental condition.

(*To be continued.*)

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 27, 1919.

THE PRESIDENT, DR. CHARLES H. PECK, IN THE CHAIR.

Introduction of Resolutions.—Dr. SAMUEL J. KOPETSKY introduced a resolution stating, in effect, that the objects of the Medical Society of the County of New York were twofold: first, the regulation of the practice of medicine in the county of New York and seeing that the laws pertaining thereto were enforced, and second, the promotion of scientific medicine. It had been the custom at the stated meetings to have an executive and a scientific session, but the business of the society had increased to such an extent that it was crowding the scientific discussions into the background. He therefore offered resolutions amending the constitution and by-laws of the society so that the business of the society could be transacted by a representative body or House of Delegates of the Medical Society of the County of New York. Under the plan proposed there would be one representative for every twenty-five members, or about 112 delegates. They should have one meeting each month or as many as were necessary to transact the business of the society. In addition to this there should be the meeting for all the members for the discussion of scientific subjects. The changes in the constitution and by-laws that would be necessary to effect this change were presented.

DR. MORRIS STARK then presented resolutions proposing that instead of such a radical change in the organization of the society the order of procedure be changed so that the scientific session should come first and the executive session should follow.

DR. WILLIAM S. GOTTHEIL introduced resolutions calling for a change in the constitution so that the clause defining the qualifications for membership in the society should include the additional qualification that the applicant be "an American citizen."

As these three resolutions involved changes in the constitution and by-laws it was directed that they be printed and submitted to the members of the society for their consideration before the next meeting.

DR. EDEN V. DELPHEY introduced resolutions instructing the delegates from the Medical Society of the County of New York to the meeting of the House of Delegates of the Medical Society of the State of New York to be held on November 22 to stand unqualifiedly opposed to Compulsory Health Insurance.

These resolutions were passed.

Medical Guilds.—Dr. ABRAHAM KOPLOWITZ of Brooklyn, on motion, was given the privilege of the floor for the purpose of explaining the organization of the Medical Guild. He stated that in Kings County the doctors, druggists, and pharmacists had organized for mutual protection against vicious legislation. The Medical Guild was composed of representatives of the regular organizations of these professions, the County medical society taking the lead. The affairs of the organiza-

tion were administered by a house of delegates and a board of directors, the house of delegates having one representative for every fifty members. The Professional Guild was not afraid of going into politics and the house of delegates included a man from each Assembly District. They had also decided that doctors, dentists, and druggists not belonging to any society should be admitted. There were already twelve societies in the State organized along the same lines and he was desirous of seeing a branch of the organization in New York County. He felt that this organization would be powerful enough to control legislation at Albany affecting the professions of medicine, dentistry, and pharmacy.

Dr. J. P. Davin opposed the organization of a branch of the Professional Guild in New York County on the ground that the medical profession could take care of itself without the aid of druggists, dentists, and veterinarians.

Cerebrospinal and Vascular War Wounds and the Results of Their Treatment.—Dr. Harold Neuhof presented this paper in which he stated that many of the lessons learned from craniocerebral wounds of war had their application in civil cranial surgery. The methods of treatment of complications at operations for cerebral wounds had clearly defined methods to be employed in cerebral operations in civil life. The treatment of soiled wounds or compound fractures of the skull in civil life had a close parallel to that of gunshot wounds and similar satisfactory results could be anticipated. A hernia cerebri or brain abscess following such lesions should be even more infrequently encountered than in war wounds of the head. This unfortunately was not yet the case and such results would not be arrived at until the antiquated methods of incision or partial incision with drainage of the damaged brain were replaced by painstaking complete excision and primary closure. In work at the Base Hospital the patients with head wounds, the majority of whom had been operated on in the front area, fell into two classes of about equal number: one in which the wounds had been primarily closed, and the other in which various methods of drainage had been employed. The large majority of those who had been subjected to an operation completed by primary closure of the scalp did well. However, infection developed in the wounds in some cases, requiring reoperation at the Base. At such secondary operations retained loose bone fragments, bits of cloth, etc., were found, and drainage with subsequent attempts at sterilization of the wounds had to be employed. Most of these patients did not progress satisfactorily either immediately or later. The best ultimate outlook in serious head wounds existed after complete operations performed at hospitals in the advanced zone; operations not completed were followed frequently by serious and ofttimes fatal complications and delayed primary operative procedures performed at the Base Hospital generally had disastrous sequels. In view of these facts, Dr. Neuhof stated that when he was sent to take charge of a neurological team at a British Casualty Clearing Station in Flanders, in the Fall of 1917, he decided that complete operation should be done, whenever feasible, upon all wounds under his care. To ascertain the ultimate results of the operative procedures employed a careful follow up of the patients was carried out. Reports had been received from more than 80 per cent. of the seriously wounded who recovered from operation and these reports now covered a period of one to two years since operation. The writer described the type of material under their care, stating that as the hospital was a general one many of the patients were suffering from wounds other than cranial; the physical signs and neurological manifestations that were present, and the operative technique that was employed. He believed that the technique of the operation had a very definite relation to the results obtained. At first they used general anesthesia, but later they concluded that by using local anesthesia the increased intracranial tension of inhalation narcosis was eliminated, bleeding greatly reduced, and the operative manipulations more delicately carried out. The whole plan of the treatment was based on the operative elimination of infective material from the brain, and its success was entirely centered on this. Therefore he held that the principle of the repair of the dural tear was correct. Undoubtedly it reduced the chances of recovery in some cases by closing in infected foci that were left in the tract of the wound; however, the outlook for success in such instances was, from the outset, unsatisfactory. The dural tear was sutured in the majority of the cases, but the dural loss of substance was too great for suture in 18 cases. In these, transplants of fascia lata were employed, since it had been shown experimentally and clinically that fascia, when implanted into dural gaps, became replaced gradually by a firm fibrous connective tissue lined by a layer of cells continuous with the dural endothelium. Follow-up records had been obtained from almost all who recovered and there had been no manifestations that could be referred to the transplant. Complications at operation were not frequently encountered, and most of them were controlled without difficulty. Bone wax was used for bleeding from the bone, ligatures for torn cerebral or meningeal arteries, bleeding from the brain substance of cerebral veins was controlled by pledgets of cotton. The scalp defect was completely closed in almost every case. There was but one instance of cerebral hernia following operation and that occurred in a penetrating wound in which infection developed in the suture line of the dura. As far as the head wounds were concerned the causes of death were most frequently ventriculitis and meningitis, following wounds penetrating the ventricles. Concerning the immediate functional results, the majority of paralyses began to improve before leaving the hospital. No paralyses developed after operation that were not present before. All of the patients with aphasia showed improvement while at the hospital. The total mortality of the operated head wounds was 22 per cent., and this referred not only to deaths in the hospital but to those learned about by follow-up reports, and included deaths from other causes than the cranial wounds. The mortality of the cranial wounds with dural penetration was 42 per cent. The ultimate results, as determined by the follow-up covering one to two years, showed not a single case of hernia cerebri, meningitis, or brain abscess. Up to the present there have been two results that suggest the existence of petit mal but as yet only one of generalized seizures. In view of these results the ultimate prognosis for patients with craniocerebral wounds after compelte early operations was far more optimistic and cheering than was generally held to be the case.

Concerning gunshot wounds of the spine, most of those with grave paralysis, just like the severe cord crushes in civil life, presented a hopeless outlook. When destruction could not be equivocally established by *x*-ray and clinical examination, the writer believed exploratory laminectomy was indicated in the hope of encountering remediable conditions. The latter proved to be true in three of twelve patients in whom he performed exploratory laminectomy. In a group of four cases of recent spinal wounds with massive paralyses and sensory loss in which operation would generally have been considered contraindieated, he found the dura intact and the immediate and distant results were surprisingly good.

One of the most frequent conditions with which they had to cope at the Base Hospital was secondary hemorrhage. This subject had been particularly studied by Dr. St. John and the writer. In their year's experience at the Base Hospital 65 a total of 2,332 operations were performed for the control of such hemorrhages. He used the term "infective" rather than "secondary" hemorrhage because their study demonstrated that infection was the cause of the hemorrhages encountered. The average time for the onset of bleeding was thirteen days, but ranged from five to forty-seven. The danger from hemorrhage proved to be over only when infection had ceased. In these cases of secondary hemorrhage microscopic examination showed all the signs of infection in the eroded parts of the artery, and bacterial stains revealed various organisms in the thrombus that was frequently present, as well as in various coats of the diseased artery. Special attention should be paid to vessels of any size if they were in immediate anatomic relationship to an infected tract that was operated upon. This should apply to the ordinary infections of civil life as it did to those of warfare. Whatever form of

chemical sterilization was employed should be applied directly to the vessel sheaths. The Carrel-Dakin treatment had the minimal chances of being efficacious when infected tracts were not adequately laid open. Amputation was indicated in most of the infective hemorrhages arising from the popliteal or posterior tibial arteries, particularly when fracture coexisted. This principle the writer advocated and practised at the front area hospital. At the Base Hospital the indications for the amputation of the lower extremity in the presence of infective hemorrhage coexisting with fracture became progressively more radical. In amputating they advocated when the patient's condition permitted, exposure and ligation of the main artery at a non-infected level and they were inclined toward the resection of the accompanying vein even when it showed no visible involvement. Dr. Neuhof also discussed the treatment of traumatic aneurysms and advocated fascial transplantation for certain types of arterial defects in aneurysms of the major vessels, and stated that experimentally he had shown that large lateral defects of the major arteries, including the thoracic and abdominal aorta, could be replaced by fascia lata sutured into them. The results were satisfactory physiologically and functionally. He had employed fascial transplants in two cases of aneurysm of the popliteal artery and the patients, after almost two years in the first case and over a year and a half in the second, reported that they were in good condition.

Dr. John F. Connors said that this paper ought not to be passed by without discussion. Dr. Neuhof had done a great deal in advancing their knowledge of the treatment of craniocerebral injuries. One of their greatest problems was secondary hemorrhage. He was glad Dr. Neuhof had changed the name from secondary to infectious. Finding that these hemorrhages were due to infection was a point of great value. Another thing they had learned was that when they ligated an artery its accompanying vein should also be ligated. Another point to be brought out was that in traumatic injuries to the arteries one could use a vein to cover the defect in the artery. The only case in which he had made a failure by this method was in a hemorrhage from the popliteal artery, and he felt that this would not have been a failure if an orthopedist had not taken the case and manipulated the limb. In this case, after manipulation of the limb, a hemorrhage occurred and the patient died.

Dr. Howard Lilienthal said the paper was of interest and value because of the exposition of the newer principles of cerebrospinal surgery and the treatment of war wounds, but it was of even greater value because it showed that very careful records had been kept and the patients followed up to see the ultimate results. That was a very important point and the one that stood out most strikingly in the paper. Secondary hemorrhages had been interesting to him also. In the older days they had been told that secondary hemorrhages usually occurred between the twelfth and sixteenth days after the injury and that that was the dangerous time. That was the time when the sloughs began to clean off, leaving the wall of the artery thin or breaking through so that there was a hemorrhage from the artery. He believed that at times the use of an antiseptic that was a blood clot solvent or a tissue solvent was responsible for a hemorrhage because it cleaned off a wound quicker than Nature would clean it off or than if it were allowed to go longer, when the blood clot might organize. As to the use of Dakin's solution, Carrel himself had said that in cases in which large vessels had been wounded Dakin's solution must be used with great caution.

Further Experiences with Roentgen Examination of the Abdominal Organs Following Oxygen Inflation of the Peritoneal Cavity (Pneumoperitoneum), with Lantern Slide Demonstration.—Dr. Arthur Stein and Dr. William H. Stewart made this presentation. Dr. Stein reviewed the development of this method, which he said had been outlined by them in a preliminary report which appeared in the *Annals of Surgery* for July, 1919. Their own adoption of this promising method dated from the spring of 1919 and by improving on the technique they had endeavored to show distinctly the parenchymatous organs in themselves, their mutual relations, as well as the pathological changes in these organs. The first report in this country on Roentgen examination of the abdominal organs following oxygen inflation of the peritoneal cavity was read by the speaker and Dr. Stewart in part before the American Association for Thoracic Surgery, June 9, the American Gastroenterological Society, June 10, and the American Surgical Association, June 16, 1919. Since that time the application of abdominal inflation to radiographic purposes had yielded very satisfactory results in their experience and had more than justified their expectations of its diagnostic value. The procedure had now been utilized by them in forty-six cases without untoward effects in any instance, although two of the patients were young children. They had slightly modified and simplified the method described by them in the *Annals of Surgery*. They no longer used the rubber bag containing one gallon of gas, nor did they need the pressure gauge. The outfit required was very simple, consisting of an oxygen tank, rubber tube, and lumbar puncture needle. The needle was inserted about two fingers below the umbilicus in the median lobe or if an old scar was present two fingers to the left and two below it. The patient was prepared for this procedure as for any *x*-ray work. One-sixth of a grain of morphine was given about a half hour beforehand to take the edge off of any pain that might be experienced. The point where the needle was inserted was cleaned with tincture of iodine and then frozen with ethylchloride. The needle was slowly inserted as far as the fascia. A very gentle pressure would then push the needle through the fascia and peritoneum into the peritoneal cavity. The abdomen was then slowly filled with an amount of gas that varied individually. The gas or air did not necessarily have to be sterilized. Experiments and practical experience with the method had shown that the elasticity of the living intestines permitted them to recede before a slowly intruding sharp body such as a needle and no trouble in this respect had ever been encountered by them or by any other observer. They had noticed that about one-third of the patients complained of marked pains in the shoulders following distension of the abdomen to its full capacity. Occasionally dyspnea appeared. No heart symptoms had accompanied the inflation except a slight rise in the pulse rate. They had found that occasionally pains did not start until late in the evening, and in this case it was advisable to elevate the foot of the patient's bed on the principle that air always rose to the highest point, thereby confining the oxygen to the lower pelvis and reducing the pressure against the diaphragm. They had now decided on the fixed rule that an hour or an hour and a half should elapse following the inflation before the patient was roentgenographed, in order that he might accustom himself to the distension of his abdomen. As far as the absorption of the gas within the abdominal cavity was concerned, it varied individually from several hours to a few days. By this procedure they had shown the liver and spleen as a whole in their normal as well as diseased condition, the spleen, diaphragm and diaphragmatic spaces, coils of the large and small intestines (without bismuth filling), enlarged intraabdominal glands, the mesenteric artery with its branches, carcinoma of the ascending colon, the female genital organs in their entirety, including tumors of the same. With reference to adhesions, postoperative or the result of chronic inflammatory processes, they were inclined to believe that their existence involved no serious danger of perforating the intestines. As to contraindications, the existence of acute abdominal conditions such as acute appendicitis or peritonitis naturally prohibited the employment of the method of abdominal inflation. It was contraindicated in known cases of valvular disease of the heart. A certain type of elderly persons, notably men who had used alcohol to excess, did not lend themselves to the employment of this method. This method of inflation possessed possibilities for diagnostic purposes without the accompanying roentgenological examination. A patient with a large abdominal tumor which had been diagnosed by certain physicians as a tumor of the uterus and by others as a tumor originating in the urachus or umbilicus was transported to them for examination. After inflating the abdomen it was possible to demonstrate that the tumor was freely mov-

able and that no connection existed between it and the abdominal walls, as a quantity of free air was found between the tumor and the latter. It was precisely for the elucidation of diagnostic problems which had so far baffled the ingenuity of the clinician that this method should be reserved, and entirely new vistas would be opened up in cases of this description. It must be emphasized that this method of Roentgen examination of the abdominal organs following oxygen inflation of the peritoneal cavity should be reserved for suitable cases in which great advantage was seen to attend its adoption.

Dr. William H. Stewart gave a lantern slide demonstration illustrating the paper. He said there was very little to be added as Dr. Stein had brought out the chief points. The inflation with oxygen took but a few minutes, but the roentgenological examination took a great deal of time.

Dr. John F. Conners said that he had seen some of these cases and was convinced that we had in pneumoperitoneum another valuable addition to our armamentarium.

Dr. Howard Lilienthal said that this was the second time he had seen the pictures and he believed the method would be of enormous value and would widen the scope of *x*-ray diagnosis in medicine. He asked if they had any pictures showing gallstones or kidney stones as he would like to know whether the method had been tried out in those cases. Dr. Stein had referred to the method the speaker had devised for determining the location of missiles in the chest. That was devised without any knowledge on the part of the speaker of the work that was being done in pneumoperitoneum. If a missile was in the chest and they wanted to find out whether it was in the lung, or possibly in the heart, or in the pleural or pericardial cavities, as in one instance in which the heart kicked the bullet with every pulsation, they allowed air to enter the chest through a cannula. A fluoroscopic examination was made before and after the entrance of the air. If a bullet was imbedded in the lung, after the lung was collapsed with air in the pleura the bullet would be shown at some distance from where it was at the first examination. It was somewhat like the method described and illustrated so beautifully this evening.

Dr. Willy Meyer said he was sure that the entire profession would feel grateful to their colleagues in New York who had taken up this most interesting method which marked a great advance in radiography. The main point to be brought up was the possibility of accident, especially if adhesions were present. Under such conditions a person not experienced in the use of the method might puncture the intestines, even though, as Dr. Stein had said, the living intestine receded before a sharp object. For these reasons he thought the method should be used only when no other method served to clear up a diagnosis; in such a case it was indicated, but it should never be used simply out of curiosity. As to the technique, the proper place to introduce the needle was below the umbilicus in the median line. Furthermore it stood to reason that it was just as important to know the amount of oxygen that was introduced into the abdomen in pneumoperitoneum as it was to know the quantity of nitrogen introduced into the chest in pneumothorax. They should find out how much could be introduced without giving pain. If that was done and the injection made under aseptic precautions a great step forward would have been made.

Dr. Howard Lilienthal warned against the use of this method in cases of tuberculous peritonitis of the fibrous type. The cases shown in the pictures were cases of tuberculous peritonitis with ascites.

Dr. J. Bentley Squier said he had employed the method in but one case, so his experience was limited, but it showed so prettily a renal lesion that he wished to exhibit the slides and to get Dr. Stewart to interpret them. The subject was a man who had had a testicle removed for what was thought to be a large sarcoma of the testicle. He came back later with a large mass in the abdomen. The diagnosis made by palpation was that there was a large tumor in the loin retroperitoneally. An exploratory operation was done and a tumor of the kidney revealed. He removed the kidney with two-thirds of the ureter. It was a question whether the tumor was of embryonal type or a sarcoma. The slides showed how the spleen could be shown not to be the seat of the tumor.

Dr. Edward Wallace Lee said this beautiful demonstration had proved one thing. They frequently had cases which on physical examination showed no pathology and in which even roentgenological examination after the administration of bismuth and barium showed no pathology, yet at the same time the patient suffered from distress in the abdomen. These pictures showing adhesions were a wonderful demonstration of the fact that with this method the diagnosis might be cleared up in patients suffering from abdominal distress due to adhesions.

Dr. Stein, in closing, said that so far as gallstones were concerned it had not been their good luck thus far to find them, though they were hunting for them. He fully subscribed to what Dr. Meyer had said. They were extremely careful to use this method only where it was absolutely indicated, only in cases in which the *x*-ray could not make the diagnosis without it, and for those cases alone the method should be reserved.

Dr. William H. Stewart said that there was no exact quantity of oxygen determined upon as yet, but they were using less than at first and were able to get the desired effect without any distress to the patient. The dose had to be adapted to the individual patient and depended to a great extent on the degree of relaxation of the abdominal walls. In regard to Dr. Squier's slides, the important point was that the spleen had no connection with this growth. The slide showed an irregular enlarged kidney extending down to the crest of the ilium.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 3, 1919.

SECTION ON SURGERY.

Dr. Seth M. Milliken in the Chair.

Fractured Internal Table—Lacerated Brain.—Dr. H. A. Haubold presented this case. He said that what actuated him to show these patients was the impression that during the last few years the decompression operation as such had been confused with brain surgery until every brain operation was spoken of as a decompression operation, especially if it was employed for the relief of trauma. The indications for opening the skull now were no different than before any one had thought of decompression, but if given 500 cases of brain injury some men would use the decompression operation for all of them, whereas there were definite indications for opening the skull after trauma. The previous history of the patient presented was of no importance. On August 17 he was struck on the head by a fist, according to his statement, and was rendered unconscious for ten minutes. He then slowly regained partial consciousness. Twelve hours afterwards he presented the typical picture of cerebral irritation. A roentgeogram of the cranium showed a stellate fracture of the skull at the very dome. An interesting feature was that at the end of thirty-six hours the patient still presented the picture of brain irritation together with a tendency to cerebral compression but not the picture of cerebral compression as described. As the *x*-ray furnished evidence that the skull was fractured and the brain symptoms were not clearing up the skull was opened. The exposure revealed a linear fracture of the external and a depression of the internal table, which corresponded to a spiculum of bone, triangular in shape, driven into the cerebrum. The skull was opened with the De Martel apparatus, uncovering an epidermal hemorrhage, laceration of the brain and dura, and a sharp hemorrhage from the vessels of the pia. A spiculum of bone was removed, but the brain was not traumatized by seizing the blood vessels and ligating them; instead drainage was established so the blood could find egress and thus avoid an increase in the hematoma. It was found that the fracture of the internal table was disproportionate to that of the external table. The following day the patient sat up in bed and the picture of cerebral irritation had cleared up. From this time the patient made a good recovery.

Dr. Edward Wallace Lee asked what covered the place where the bone was removed.

Dr. Haubold replied that there was nothing; the flap was put back and drainage established. The opening corresponded to the center of the right leg in the motor cortical zone. There was some bleeding into the meshes of the pia; irritability had entirely disappeared.

Cyst of the Motor Cortical Zone.—Dr. Haubold also presented this patient who, he said, was injured about three years ago. While working as a lumberjack a tree fell upon him and rendered him unconscious. He was taken to the Watertown Hospital and from the defect remaining it appeared that he must have sustained a compound fracture. Six months later he developed a typical Jacksonian epilepsy, beginning always in the left arm and extending in both directions and finally becoming general. At the end of another six months he was having these Jacksonian epileptoid seizures three times a week. Nine months after the injury he came to a hospital in this city where an osteoplastic resection was done over the motor cortical zone on the right side. The surgeon wired the osteoplastic flap back in place, a procedure which he thought was not being generally employed. However the Jacksonian epileptoid seizures were not helped and he was having as many as two or three a day. It was then decided to make a further investigation, and on December 29, 1918, eight months after the *x*-ray (which was shown) this was done. A diagnosis of a lesion of the right motor cortical zone was made and after turning down the osteoplastic flap it was found that the dura had not been opened at the previous operation. What had probably happened was that the injury was so near the longitudinal sinus that the surgeon had encountered brisk hemorrhage and had not attempted to make further investigation. The dura was incised corresponding to the measurements on the roentgenogram and a cyst the size of a small English walnut was discovered and excised. A fascial transplant was made, sutured into the dural defect, and the wound closed with drainage. The patient had an epileptoid seizure the next day, but from that time the attacks became less frequent. As the wound did not heal it was decided to reopen it. It was found that there was some sloughing of the flap, but in spite of the long suppuration the brain was perfectly protected. For some time after this a small sinus persisted, but the epileptoid seizures became less and less, and he had not had one since August 1. This was not to be regarded as an absolute cure of Jacksonian epilepsy, but the operation seemed justifiable inasmuch as the patient was able to work when he wanted to do so; very rarely had a seizure, and was a much happier man.

Dr. Edward Wallace Lee asked Dr. Haubold if he had done anything with the clot found in the first place. He said that in considering these cases of skull injury he believed it was a very good rule to follow certain indications. If there was injury to the soft parts they should be examined very carefully. If there was absolute indication of fracture, trephining was indicated; if there were brain symptoms without evidence of fracture, trephining was indicated because one could have a fracture of the internal plate without possible symptoms or signs of fracture of the external plate; and if there were no evidences of fracture and no brain symptoms the injury should be treated as an ordinary simple trauma. Dr. Haubold spoke as though he doubted that the fracture was inflicted by a blow with the fist. He knew that the fist could break the internal plate for he had seen it happen. He had also seen fractures of the internal and external plate inflicted with a broomstick. Dr. Lee also asked what evidence we gained by making a spinal cord puncture in these cases. He said he was connected with a hospital where he was called quite often and asked to have a spinal puncture made to get evidence of fracture of the skull. He could not see the advantage of this and left these cases alone and they had no further trouble. He would like the question answered by some one who did a great deal of brain surgery. It was his impression that spinal cord puncture was done too often.

Dr. Haubold, in closing, said that as far as spinal puncture was concerned he thought it gave information as to whether there was blood in the spinal fluid. If, however, there was a clear picture of depression he thought that there was some danger attendant on this maneuver.

Disabilities of the Knee Joint.—Dr. Walter A. Sherwood presented this paper which was based on 400 cases observed in the general surgical and orthopedic wards of U. S. Army General Hospital No. 1 during the period of military preparedness. It did not include the complications and sequelæ of the wounds of war. Most of the material was arranged and classified by Captain M. L. Jones, one of the writer's assistants in charge of the orthopedic wards, and it was therefore to be considered as a joint contribution of the orthopedists and general surgeon. The cases studied were classified as follows: (*A*) Functional conditions, hysteria, neurosis, etc., 22 cases. (*B*) Organic conditions, including (1) external derangements: (*a*) traumatism to soft parts, including superficial wounds and contusions, 27 cases; (*b*) bursitis, 10 cases; (*c*) bony conditions which interfere with function but do not penetrate the joint, 42 cases; (*d*) sprains and rupture of ligaments, 16 cases; (*e*) strains of muscular attachments, 26 cases; (*f*) injury to the tubercle of the tibia, 3 cases; (2) internal derangements; (3) the different varieties of arthritis, including (1) ordinary infections, 90; (2) gonorrheal infections, 30; (3) luetic infections, 4, and (4) tuberculous infections, 2; (*a*) injury to the semilunar cartilage, 17 cases; (*b*) loose bodies in the joint, 42 cases; (*c*) retropatellar fat pad conditions, 2; (*d*) injury to crucial ligaments and tibial spine (mostly associated with dislocations), 9; (*e*) fracture involving the joint, 38 cases; (*f*) injuries to patella, including (1) periostitis, 2; (2) dislocations, 6, and (3) fracture, 12 cases. Each of the above conditions was reviewed briefly from the standpoint of etiology, clinical signs, and *x*-ray findings, together with appropriate treatment, operative and otherwise. Emphasis was laid on the various methods of obtaining the best functional result possible in the shortest period of time. The paper was illustrated by a series of *x*-ray reproductions portraying the various lesions above discussed. The writer concluded as follows: (1) With careful clinical and *x*-ray study, most disabilities of the knee joint might be accurately diagnosed with comparative ease. (2) The disability which followed many of the more serious injuries to the knee joint should be relatively slight provided an accurate diagnosis was made and appropriate therapeutic measures were early instituted. (3) Physiotherapy intelligently applied under proper supervision was a neglected but most important adjuvant both in post-operative care and as a definitely indicated therapeutic measure in most of the non-operable lesions of the joint. (4) A closer cooperation between the general surgeon and the orthopedist was essential for the satisfactory study and management of all joint lesions. A borderline was purely an imaginary or theoretical one and was not in the best interest of the patient. (5) The major surgical procedures involving the knee joint should be attempted only by the surgeon of large basic experience and training.

Dr. George E. Brewer said that this interesting and instructive paper ought not be allowed to pass without discussion. It gave valuable points in regard to diagnosis and treatment. In speaking of fractures of the patella the reader of the paper made a statement to the effect that fixation by sutures was only mentioned to be condemned. For many years that was a favorite method and the speaker's plan was to drill obliquely through the fragments and to draw them together with chromic catgut. He did not recall a bad result when this was done, and it was effective even where the fragments were widely separated. Some time later we began to suture tears in the lateral expansions of the aponeurosis on either side, and also placed sutures in the periosteum. If there was no tension this was satisfactory, but if the fragments were widely separated they might subsequently be torn apart. Dr. Brewer mentioned two instances in which this occurred.

Dr. Seward Erdman asked, in reference to injuries to the semilunar cartilages, whether Dr. Sherwood had ever gained any assistance from the *x*-ray in making the diagnosis; if so had he used the recently proposed method of injecting oxygen into the joint in order to bring out the shadow of the cartilages against the oxygen-filled cavity of the joint. He also asked what were to be considered sufficient indications for opera-

tion in this class of cases in which the diagnosis hinged so largely on the patient's own statements. Should not the surgeon insist that he himself be a witness of one of the attacks of disability and synovitis?

Dr. HEINRICH F. WOLF said he wished to speak not for strictly surgical but for infectious cases. The speaker had advised fixation in all these cases, though he did say it should be as short as possible, but I feel that he should be a little more precise in his statement. Immobilization should be as short as possible and only resorted to when really necessary, and not in the form of a plaster cast, but with something that can be taken off. He recalled that he had read a paper on the treatment of infections of the joint in which he advocated massage in a very early stage in gonococcus and streptococcus viridans infections and the results were very good, if the massage was started very gently. It could be begun one or two weeks after the onset of the disease. Such gentle massage had been shown, not to give pain, but to relieve it very rapidly. Frequently pain was due to jarring the joint and if the joint was kept well supported the pain was not severe. The speaker did not mention Bier's hyperemia which though it did not cure the condition relieved it very much. Immobilization should be resorted to only when pain was so severe that sleep or rest were impossible.

Dr. C. G. HEYD said that in fractures of the patella Dr. Sherwood said one should wait before attempting operation. They did not think that they ought to wait before reducing a Colles fracture or a fracture of the femur, so why wait before reducing a fracture of the patella? Drilling a hole in order to place a suture to draw the fragments together was not often necessary if the fracture was reduced at once.

Dr. GEORGE E. BREWER recalled that Dr. Carleton Flint had collected and analyzed many hundreds of cases and found that seven times as many postoperative infections of the joint occurred in those operated on before the fifth day as occurred in those operated on after that time. That was because immediately after trauma the tissues had lost to a certain degree their resistance. It was best to delay operation for at least five days. That had for many years been the rule on the speaker's service of the Roosevelt Hospital, and during over twelve years he never knew of an infection occurring in such a case, on either surgical service.

Dr. J. F. CONNERS asked how long Dr. Sherwood kept the fractures immobilized.

Dr. SHERWOOD, in closing, said his statement with reference to suturing with silver wire was perhaps too sweeping. It was an opinion based on his experience in civil life rather than on army experience because he had not seen many fractures of the patella in the army. It was his belief that drilling and the use of silver wire had been abandoned except where the fragments were very widely separated, and even in those cases he thought other methods preferable. His method had been simply to suture the torn ligament with chromic gut, suturing the lateral tears in the fascia as carefully as the ligament itself. In regard to Dr. Erdman's question in reference to the dislocation of the semilunar cartilage being seen with the *x*-ray, in the majority of cases they had not been able to discover anything with the *x*-ray except narrowing of the interarticular space in the affected side. He had never used injections of oxygen into the joint. The cartilage did show faintly in a few of the *x*-ray plates, but in the majority one had to rely upon the sense of touch and the clinical history. In regard to the time for operating on a fractured patella, it had been his custom to wait until the acute reaction had subsided. One was less liable to have infection if one waited several days and that was the risk most to be feared in opening the knee joint. The question was asked how long a fracture involving the knee joint should be immobilized. In one case, the illustration of which was shown in one of the pictures, the immobilization was for ten or twelve days and then active and passive motion was begun, and it seemed in this instance that it was due to the persistent effort to keep this joint moving that subsequent disability was prevented. No definite time could be stated, however, to cover the whole situation, but each case should be judged individually, bearing in mind the necessity for mobilization as early as was consistent with safety and good position.

Some Improvements in the Mechanical Treatment of Fractures.—Dr. GEORGE W. HAWLEY made this presentation. He stated that in France alone there were 150,000 fractures with complications that required further surgical interference. Any one who had come into contact with the various surgical services in England and France and on the Continent at the end of the war was impressed by the effort everywhere to standardize splints. In making a survey of this subject several features stood out: First, the general principles of treating fractures now were the same as they always had been. The most striking feature in the treatment of fractures during the past five years, and particularly military fractures, was the attention given to the mechanical treatment. Many new ideas had been developed which had improved and simplified the mechanical treatment of fractures. One need only mention the name of Thomas, Sinclair, Jones, Keller, Pearson, and many others to recall what had been done. To Dr. Blake was due the credit of demonstrating the value of a combination of traction and suspension. This method was adopted by both the French and the British. The future would probably see a more intelligent study of the mechanical problems and the relations of muscle balance connected with the treatment of fractures. It was only necessary to examine a considerable number of cases subjected to the abduction treatment to see some of the unfortunate results of this method. A fracture should not be treated merely as a broken bone but as a broken part of a motor. The time had arrived when the period of convalescence following a fracture could be shortened by one-half. He was inclined to think that the future treatment of fractures would include more accurate fixation combined with motion nearly from the beginning. For the illustrations of mechanical apparatus shown on the screen he said he claimed no particular originality. He had used the ideas of others but had endeavored to simplify construction and to adapt it to some requirements not met by the mechanical appliances in general use. Among the devices shown was a contrivance for traction without removing the shoe; heel-pin traction for reducing a fracture of the tibia, which did not require a great deal of traction, but would reduce a great deal of displacement. This apparatus was especially useful in spiral and low oblique fractures, reducing them in forty-eight hours so that it was difficult to tell with the fluoroscope where the fracture was. Among the other appartus shown was a suspension apparatus which permitted the application of a plaster cast without removing any portion of the apparatus; a splint which permitted the examination and treatment of the foot without disturbing its position; an apparatus which permitted the patient to extend his own knee. The important point in reference to motion was not that the apparatus should permit a wide range of motion, but that it should permit some motion. A modified overhead suspension apparatus, a bed with wire springs so arranged that the bed could be adjusted at different angles, and a sacral lift useful in moving and lifting patients were also shown.

Dr. EDWARD WALLACE LEE said he was interested in all these new appliances and wanted to learn, yet the thought had occurred to him whether the results in the treatment of fracture in the past were so bad that surgeons had been forced to interest themselves in these things. Were the results in the treatment of fractures fifteen or twenty years ago, whether the fractures were simple, compound, or complicated, so bad that the ideas now prevailing were suggested? For nearly twenty years, Dr. Lee said, he had been a railway surgeon and fractures were very common. They had resorted to the treatment then in vogue and their results were excellent and he believed would compare favorably with the results they were getting today. Of course they did not have the very serious infected injuries that were met with in the European war, but they have crushing injuries of all varieties and traumatisms that were very serious, and their results with such injuries compared favorably with what they saw today. He wondered what had stimulated this activity and whether fractures were not being fussed with, so to speak, too much today. Were they not manipulated too much in order to get *x*-rays, etc.?

Dr. MILLIKEN said he thought he could answer part of Dr. Lee's query. Twenty years ago they did not have the x-ray and did not know whether a fracture was in exact alignment. They aimed to get a good-functional result and did not know if there was a little over-riding, but now they aimed to get the fragments back to their right position.

Dr. CONNERS asked Dr. Hawley if he considered the heel pin as good as the Sinclair apparatus.

Dr. HENRY H. M. LYLE said he had been fortunate in having the opportunity of observing the results obtained by the French Army in 1915 and 1916, and again with our own Army. Those of us who were familiar with the good work done by the English and French realized that we were but beginners in military surgery and did not achieve the proficiency of our Allies. The battle surgery of 1918 was that of 1916, with one important exception—the generalized use of traction splinting. Those who never had a personal knowledge of the frightful mortality and the disastrous after-results of the treatment of compound fractures of the femur could scarcely conceive what a great boon the use of the Thomas splint was to our forces. We all knew that gunshot wounds of the bones were responsible for more pain than all the other casualties of the war put together. The speaker was firmly convinced that the application of the Thomas splint on the field was one of the great life-saving and comforting measures of the war. Those who planned the organization that made this possible could look back upon their work with just pride. To the Field Surgeons and Corps Boys who did the actual work under heart-breaking conditions—All honor to them! They were the back-bone of the surgical treatment of the fractures. The Thomas splint had the following military advantages: transportability, simplicity, ease of application. There were modifications of the Thomas splint, and splints for special purposes which possessed many advantages, but the place for these splints was not in the zone of advance, but in the rear. Dr. Lyle said that upon the sugugestion of Dr. J. Gerster, of this Society, he had first used the Steinman pin in 1914 and was very much impressed with its advantages. In France in 1915, 1916, and 1918 he used it extensively on compound fractures of the femur and lower leg. He was able to obtain better anatomical and functional results with less pain and suffering to the wounded than by the ordinary methods. He considered it was a factor in diminishing the infection and the mortality in fractures of the femur. Accumulating reports from French and German sources confirm this opinion. Dr. Lyle said he would like to correct an impression regarding the fracture frame misnamed by many, the Balkan frame. The Balkan frame was a simple ridge pole extending from the head to the foot of the bed. The fractured leg was suspended by doubled sheets from the ridge pole. An illustration and description of the Balkan frame would be found in "Notes On Military Surgery," by George W. Crile, (*Annals of Surgery* LXII, July, 1915, pp. 1-10). From this it would be seen that the Balkan frame had no resemblance to the fracture frame under discussion. The fracture frame commonly used in the A. E. F. was designed by Dr. Lyle and made by Mr. Mills, one of the ambulance drivers attached to the American Ambulance, Hospital B, at Juilly, Seine et Marne. It was first put into use in March, 1915. Pictures of this frame were shown before the Quiz Medical dinner in the spring of 1915, and before this Section. The frame was demonstrated before Inspector General Chevasse, of the French Army. It was interesting to note that General Chevasse stated that while he was an observer for the French in our Civil War he had seen a tripod arranged for suspending a Hodgkins splint but that he considered this frame a marked improvement. The original frame was fastened by winged nuts and bolts, could be readily collapsed, fitted any bed or cot, could be adjusted on any floor, and no tools were needed to erect it. The original frame did not have the wooden trolley under the ridge bar, but the pulleys operated on an adjustable bar so that a constant level parallel to the floor could be kept when the foot of the bed was elevated. The wooden trolley was added by Dr. Blake in 1916. The original frame was more portable and adjustable than the one furnished by the A. E. F. Otherwise it was identical in principle and construction. The A. E. F. one did not have the trolley. The speaker furnished the model to the American Ambulance in 1915; to the Carrel hospital, Breton Division of the French Army; Professor Tauton, of the Val de Grace; and others, also equipping the Ambulance Longueil-Annel. As there had been a great deal of misinformation regarding the origin of this frame the speaker took this occasion of presenting the true history of it.

Dr. JOHN J. MOORHEAD said that, with reference to the Balkan frame, the idea that it was new was dissipated for him when in talking with a French surgeon in charge of a military Hospital near Compiégne he learned that this man had several overhead frames of the tripod type made, and he said the same type were used in the American Civil War and that antedated many years the original Balkan frame. There were two or three pieces of apparatus that he had been using for some few years. He had been using the Chutro modification of the Finochietto stirrup and a modification of the Steinmann pin in selected cases, and these were methods of value. The stirrup method was of use in fractures of both bones of the leg above the ankle joint. In thinking the matter over he had decided for himself to try to standardize the treatment of fractures of the long bones. For the treatment of fractures of the upper extremity there were certainly standardized methods, but in the treatment of fractures of the femur and leg we were undergoing a process of evaluation of many methods. Personally, he made two attempts at correction on the Hawley table and had the results checked up by *x*-rays taken in the antero-posterior position and in the lateral position as well. If he found the results poor he did an open operation. Supracondylar fractures of the femur were the most difficult to manage. He never introduced foreign metallic material and he never used a bone graft unless there was no tendency to throw out osseous tissue. He did not regard the bone graft used as an internal splint as satisfactory. In fractures near the ankle joint, Dr. Moorhead said, he used the Chutro modification of the Finochietto stirrup.

Dr. L. T. LEWALD said that Dr. Hawley spoke of stirrups of aluminum as being desirable for their lightness; they were also desirable for their radiability. A great many hospitals used the old heavy splints of metal and with these it was difficult to get *x*-rays.

Dr. HAWLEY, in closing, said that as to the Sinclair stirrup, they had had difficulty in making it hold and in some instances the foot went into partial toe-drop, and hence they had been using more and more the heel pin as it gave a gradual pull. As to the supracondylar fractures of the femur, he had not had much experience in the use of the calipers and Major Pearson had had difficulty in correcting posterior displacement of the upper part of the lower fragment with the calipers. He apologized to Dr. Lyle for not having given him credit for the Balkan frame. As to the remarks about the Steinman pin, it was simply a question of which was the better way to get the skeletal pull. He had seen some of Dr. Lyle's cases and they were in splendid position with the use of the Steinman pin, and Dr. Gerster used it with success. Whether the caliper was better he could not say. If the pin was put in above the os calcis instead of through it, it could be done without making an incision and the skin hugged the pin tight. There was little danger of cutting the heel cord unless there was the grossest neglect.

Need of Reform in Posology.—The terms "maximum" and "minimum" doses seem in a way of becoming obsolete. The latter especially serves no useful purpose as it now stands. We may speak of the economic dose to be given during 24 hours or more in which only that amount is used which is necessary for the desired effect, but there is no economic single dose. The term maximum dose is less desirable than that of optimum dose by which is incidentally implied a large dose when necessary. Chauffard, a French therapeutist, would use two terms for doses, viz., the dose habitually employed and the dose habitually efficacious. In an article in the *Bulletin général de thérapeutique* he states that the next edition of the French Codex will contain important changes along these lines.

SPECIAL FACTORS IN MANAGEMENT FAVORING NORMAL DEVELOPMENT OF THE CHILD.*

By HENRY L. K. SHAW, M.D.,

ALBANY, N. Y.

CONSULTANT IN CHILD WELFARE, NEW YORK STATE DEPARTMENT OF HEALTH.

The fact that a discussion of the normal development of children is included in the program of this conference is significant of the present attitude of the medical profession.

Keeping children well is more important than curing them when they are ill and I welcome this opportunity of discussing preventive medicine as it applies to children before such a representative body of women physicians.

The importance of healthy parenthood in the production of a strong, vigorous, and virile race cannot be too strongly emphasized. Every child should have the right of being well born of parents who are physically, morally, and mentally sound.

It was my privilege in 1913 to attend a meeting of the English Speaking Infant Mortality Convention in London, and at that meeting John Burns, who was at that time president of the local government board in England and a member of the British cabinet, used a couplet that has run in my ears ever since. He said, "In order to improve the race the parents should be cleanly wed, the children nobly bred, wisely fed, and firmly led." And I think the crux of the whole matter is contained in that short sentence.

It was Dr. Oliver Wendell Holmes, our distinguished colleague, who advised children to choose their own grandparents in order to insure a good healthy childhood and manhood.

The subject of eugenics is unquestionably a special factor in the production of normal children. The parable of the sower furnishes a very interesting illustration of the relationship between eugenics and environment or enthenics. You remember the sower went forth to sow, and some of the seed fell in rocky places and did not germinate, did not grow up, and blew away and was destroyed; some of it fell among thorns and weeds and they sprung up and choked it; but some of it fell upon good ground that had been specially prepared and good and abundant crops resulted.

The seed is heredity and the soil is the environment. Even good seed when it falls in bad environment among the weeds of social unrest, of poverty, of ignorance, of irresponsible parenthood, etc., will become choked, distorted, and dwarfed. Inferior seed when sown upon good ground will not necessarily bring forth good fruit, for we know like begets like, and the good book tells us that figs cannot grow from thistles and grapes from thorns; and "as a man sows so must he reap."

The first line of this couplet "The parents must be cleanly wed," is a subject that is now being taken up by the United States Public Health Service, and a country wide campaign of education is being conducted. A number of our most prominent women physicians including our chairman are now engaged in this work for the government, and I presume it will be taken up at other sessions of this conference.

I had hoped that Miss Lathrop would have presented the question of infant mortality this morning, because there is a very close relationship between our subjects. If she were to enumerate the chief causes of infant mortality, you would find that a very large percentage is preventable. The records of New York City form an interesting demonstration of the proof of this. In 1880 the infant mortality in this city was 286 deaths per thousand infants born. In 1902 that number had fallen to 168, in 1911 to 120, in 1913 to 102; and 1918, the year of the war and of the influenza epidemic, that number had been reduced to 92 per thousand living births,—a most astonishing and astounding fall in the infant mortality rate. We can show a corresponding reduction in rate, but not quite to such a low level, in the State outside of this great city of New York.

Now, these results are not accidental nor are they attributable to any one cause or any one factor, but they are due, I believe, to certain influences that were in operation the last few years that were not in operation twenty or thirty years ago. Dr. Holt pertinently asks the question, "Does God fix the death rate?" Once men were taught so, and death was regarded as an act of divine providence, often inscrutable. We are now coming to look upon infant mortality as evidence of human weakness, ignorance, and stupidity. We believe that Providence works through human agencies and that in this field as in others we reap what we sow and no less."

Sir George Newman, the medical officer of the new Ministry of Health in England, once said that to save child life is an axiom of State preservation and to remedy defect is an axiom of State economy. There is now no ultimate need of the State greater, more imperative, or more urgent than that of

*Address before the International Conference of Women Physicians, New York, September 23, 1919.

securing the health and physical efficiency of the rising generation.

A new branch of pediatries has been evolved in the last twenty years, one which is concerned with the child in health and with the prevention of disease. For want of a better name this has been termed social preventive pediatries. The older branch which devotes itself to the detection, study, and treatment of disease, unfortunately occupies almost exclusively the minds and the attention of most of our physicians.

These two branches are complementary and we should not attach an exaggerated importance to one and forsake the other. To cure, someone has said, is splendid, but to prevent is Godlike. So let us direct our chief energies to the prevention and early recognition of minor ailments and defects before they have assumed serious proportions and while still amenable to treatment.

The Chinese method possesses some advantages along the protection of public health. Public health propaganda in the various States and the work of the Life Extension Institute in this city have led the public to look upon the doctor as one not only to treat disease but also to keep it free from disease, and to keep it well. George Bernard Shaw wrote that what the mass of patients really need at the present time is not medicine or operations, but money, better food, and better clothes, and more frequent changes of the latter, and well ventilated and well drained houses.

Parents must be shown the advantages in having a thorough systematic physical examination of their children. This should be by a competent physician at stated intervals. The dentists have demonstrated the value of periodic teeth inspection, and children are now taken at regular intervals to the dentist to have their teeth examined. Automobile dealers urge their patrons to have regular inspection of their automobiles, as a matter of economy and good business. We can learn a great deal from the automobile dealers in the care of the automobile. No one buys an automobile until he has the book of instructions to show how to run it, and he learns all the intricate parts of that automobile before purchase. How many mothers receive the book of instructions regarding their baby before the baby comes, and learn something about its mechanism? The automobile needs plenty of water. If you put too much covering on it, it won't run well, especially when it is hot; it has to be properly cooled, preferably with water; it has to have the right feeding mixture; if you give it too much gas or too much air, it will not run smoothly; it must have exactly the right mixture in order to make it run properly. Its cylinders have to be kept clean and it will not stand abuse or neglect. The successful merchant takes stock, or inventory, at stated intervals to ascertain just how the business stands, and the banks request our bankbooks at periodic intervals in order to balance our account and to see just how much stands to our credit so that we don't overdraw our bank account.

Now, I believe the child is just as much entitled to a careful physical inspection of its delicate and complicated machinery, to a physical inventory, and to a balance of physical capital. In this way, and in this way only, can we ascertain the physical resources of the child and the amount of vitality available for the hard business of living. Physical defects, if any exist, are discovered and corrected before serious damage is done. As Dr. Means said, in her introduction, if this had been done twenty years ago the number of men rejected from the draft would have been very much less.

The subject of social preventive pediatrics has been sorely neglected in our medical colleges. Medical schools exist for the purpose of supplying the community with men trained to protect, improve, and prolong the public health. If they fail to do this, they fail to fulfill their complete duty. I have been unable to find any reference to this subject in the curriculum of over a dozen medical colleges. It is rather encouraging, however, to note that at the last meeting of the American Pediatric Society a committee was appointed to prepare a syllabus on social preventive pediatrics for the use of medical colleges and to use every effort to have it introduced.

I would like to read a few words from a speech by Dr. Rene Sand before the Conference of Child Welfare at Washington last May. He urges that the colleges should teach preventive medicine and even goes a little further:

> I believe we should teach sociologic medicine. There is a field between sociology, statistics, biology, medicine, hygiene, and philanthropy, which is a kind of no man's land. Some patrols start from the biology border, explore a little stretch, and then come back. The same occurs from all the borders. When two patrols coming from different borders meet each other, they sometimes fraternize; more often there is a big scientific fight. I do not mind very much this kind of fighting after having seen the other kind. The worst feature is that the patrols seldom meet, and so every bit of knowledge which one border gains about no man's land is lost for the others. There is no coordination of effort, no planning together, no teamwork.
>
> I think this could be avoided and a real need be met if we started frankly to organize that field under the auspices of Sociologic Medicine. Sociologic medicine means the medical end of social questions or the social end of medical questions, as you prefer to put it. It would have been constituted long ago were it not for the fact that it requires teaching biological, statistical, and social methods to the physicians. Now, biological methods the actual or future physician will accept without too great trouble. There will be more resistance to statistical methods, they need the use of higher mathematics and fumbling about in terrible books like the Census. But even that, the better type of undergraduates or doctors will finally admit, on account of the scientific stamp that statistics receive from mathematics. When it comes, however, to sociologic methods, the average medical man revolts: surveys, inquiries, social case work, all seem too humane to be scientific; and then they mix up with all sorts of social questions, nearly related to political questions. That is a slippery field.

I will enumerate briefly without going into a detailed description, the topics which I would include in such a course: *Vital statistics* in so far as concerns birth registration, infant mortality, infant morbidity, child labor, etc.

Prenatal work in its various forms. The interest in prenatal work is sweeping all over the country on account of the very striking results shown in New York by the New York Milk Committee some years ago, and in Boston and other cities where this work has been in operation.

The prevention of infant mortality, which includes child welfare stations, day nurseries, little mother's leagues, etc. Medical school inspection and health supervision of the child of pre-school age.

The problem of the poorly nourished child, establishment of nutrition classes, school luncheс, etc.

The prevention of tuberculosis in children. Open-air schools, preventoria, and resident sanatoria.

The prevention of dental caries. Hygiene of the mouth, with dental clinics, suitable dietaries.

The care and education of the crippled child, the blind child, and the deaf and dumb child.

The backward and mentally defective child, and all the problems associated with that great subject.

The delinquent child.

The child in industry, and the mother in industry.

The milk problem as it affects the child.

These and many other topics are closely allied to the question of preventive social pediatries. I am not aware of any college which takes these questions up in a scientific and comprehensive manner, and yet these are topics which every physician should be familiar with before leaving college.

The medical profession has not realized the opportunities for service and the fulfillment of its highest ideals in directing and assisting social welfare and educational work. By our very indifference we have allowed the non-medical social worker to grasp a very great opportunity and to gather all the credit. This work should appeal very strongly to you women physicians, and I believe it offers a wide and vast field of usefulness.

A few weeks ago at the request of Dr. Biggs, Commissioner of Health of the State of New York, I prepared a program for child welfare work that would be applicable to a city of 25,000 inhabitants or more, and with your indulgence, I will read part of that report.

In the first place, a comprehensive child welfare program would include these various agencies: Prenatal or maternity work; child welfare stations; day nurseries; the care of the child of preschool age; medical school health supervision; special education and supervision of the child in industry, the tuberculous child, the blind child, the deaf and dumb child, the mentally defective child, the crippled child, the venereally infective child, the delinquent child, and the illegitimate child.

Provision should be made for medical and nursing care and treatment in hospitals or in the homes for all sick infants and young children not having a private physician and nurse. A system of social service work in the homes would be included in this program.

Recreation should be provided for the children of all ages under trained supervision. The milk supply should be under rigid supervision from the pasture to the home.

Special efforts to foster education in child welfare work would constitute a most important feature of this program. Instruction in child hygiene and health in the schools. Talks to mothers at the schools, child welfare stations and so forth. Instruction of the public by meetings and addresses, exhibits, films, posters, distribution of literature, articles of the public press and so on.

A survey of the vital statistics, milk production and distribution, school sanitation, hospital facilities, industrial activities of women and children, housing conditions, as well as the social and economic factors, is a necessary first step in order to locate the various child welfare activities where the need is most urgent. It would reveal not alone the child welfare needs, but would disclose what might be called the child welfare assets of the city.

The child welfare station embraces several activities including the care of the mother before the baby's birth, the infant after birth, and the child of preschool age. The number of such stations depends on the local needs, as shown by the survey.

As a general rule 300 infants and 750 children of preschool age should constitute the limit for effective work of any one station.

Prenatal and maternity clinic: This includes supervision of the midwife and visiting the homes of hospital cases after their discharge. There should be sufficient clinics held and nurses employed to care for all cases not receiving supervision from private physicians or a maternity hospital.

The attending physician takes complete physical examination as early in pregnancy as possible, uranalysis twice a month or more frequently if necessary, blood pressure determination and Wassermann tests when indicated.

The nurses visit the homes, urge mothers to attend the clinic every two weeks, refer necessary cases to dental or venereal clinics, instruct the mothers in the hygiene of pregnancy and early infancy, provide for confinement in a hospital or at home by a physician, make daily visits for at least five days after confinement and two visits the second week, see the proper prophylactic treatment is given the eyes after birth, attend the prenatal clinics, and refer every infant to the child welfare station.

Child welfare work: The attending physician should be present at the station at least three times a week to examine infants and children of preschool age, give advice and directions concerning the diet, clothing, and care of the children, and supervise the measuring and weighing of the children.

A dentist should conduct regular clinics for the treatment of the teeth of children of the preschool age.

One child welfare nurse should be supplied for every 100 babies enrolled. The child welfare nurse interviews the mothers and prepares the babies for examination at the station. She keeps the records and weighs and measures the children. She arranges for lectures and talks and gives practical demonstrations to the mothers. She visits and instructs the mothers in their own homes how to clothe, care for, and feed the baby. When the physician finds defects in older children, she goes to the homes and sees that these defects are remedied and proper hygiene and medical treatment are provided.

A dietitian could do very valuable service not only in teaching the mothers how to purchase food economically in regard to food values, but in demonstrating to them in their own homes and with their own utensils how to properly cook and prepare the food. The welfare of the child and the family depends very largely on diet and nutrition.

A social worker should be on the staff of a child

welfare station. She should do social service work and keep records of the family surroundings. From her study of the family and home conditions she would suggest the solution of domestic problems.

The following is a suggested budget for one child welfare station:

Rental of house for clinics, nurses' residence, and so forth, $1,200.

Two physicians, $750 each; dentist, $500; which totals $2,000.

Nurses: Head nurse, $1,500, prenatal nurse, $1,200, child welfare nurses (2), $2,400; total $5,100.

Dietitian, $1,200.

Social worker, $1,200.

Furnishing and equipment, $1,500.

Milk for needy cases, $500.

Janitress, $500.

Miscellaneous expense, $1,200. Making a grand total of $14,200.

In the budget I included the pay of the physicians, because I think there has been a great effort in our child welfare stations in this country to get the free services and all they can out of the physician. Everybody else is paid and the physician has to do his or her work free of charge. They devote much time to the work, and receive only the thanks of the community—and not always that. I believe the physician in attendance is as much entitled to pay as the nurse or anybody else.

The day nursery: There should be adequate provision for the day care of infants and young children between nine months and six years of age whose mothers are employed in industry. The staff should consist of matron, kindergartner, and sufficient domestic help. Medical supervision is necessary, and the attending physician should visit and inspect the nursery at least once a week. He should make a complete physical examination of every child on admission and give recommendation for the diet and general health care of each individual child.

Medical school health supervision: A comprehensive system of school health supervision should be established for the purpose of preventing, detecting, and correcting physical defects in school children and for instructing them in the rudiments of personal and public hygiene. The physicians should devote their entire time to this work. There should be one school nurse and one part time dentist to every 2,000 school children.

For a budget for a city having 10,000 children in the schools, is the following: one full-time physician with a tentative salary of $3,500; an assistant physician at $2,800; five school nurses at $6,000; five part-time dentists $2,500; and miscellaneous expenses and so forth, $1,200; making a total expense of about $16,000.

Social workers: I believe there is a distinct field for the social worker. The services of trained social workers should be utilized in the oversight of children employed in industry. They should see that the child labor laws are enforced in regard to the hours of employment, minimum wage, education, and sanitation. Arrangements for a complete physical examination before the labor certificate is granted should be made, as well as for semi-annual examinations, until the child reaches the age of eighteen. They should have supervision of the juvenile court cases. They should investigate the cases of dependent children before placing them in homes and institutions. They should arrange for the institutional care for mentally defective children and their education. They should visit and advise the parents of crippled children, blind children, and deaf and dumb children, regarding education and specialized institutional care. Provision should be made for active cases of tuberculosis in sanatoria and for placing predisposed children in open-air schools and preventoria.

I have read this program to you because I believe it is practical and serves to illustrate what we are trying to do in this country along the lines of child welfare work.

I want briefly to consider the question of the school child, and I again quote from Sir George Newman, who, in a recent report to the British Board of Education, proposed the following as minimum standards to insure to all children a sound and liberal education both of its mind and body:

First, that every child shall come periodically under direct medical supervision and if found defective shall be followed up;

Second, that every child found malnourished shall, somehow or other, be nourished, and every child found verminous shall, somehow or other, be cleaned;

Third, that for every sick, diseased, or defective child, skilled medical treatment shall be available;

Fourth, that every child shall be educated in a well ventilated schoolroom or classroom or in some form of open-air schoolroom or classroom;

Fifth, that every child shall have daily organized physical exercise of appropriate character;

Sixth, that no child of school age shall be employed for profit except under improved conditions;

Seventh, that the school environment and the means of education shall be such as can in no case exert unfavorable or injurious influences upon the health, growth, and development of the child.

There is a growing tendency to include health instruction in contradistinction to physiology in our public school curriculums. Childhood is the period when health instruction is most effective, and the lessons learned in the schools will be carried into the homes and applied in the family life. Adults are poor pupils in any school and it is very hard for them to unlearn and discard the faulty health habits of their childhood.

Dr. Thomas E. Finegan, Commissioner of Education for the State of Pennsylvania, who is a lay educator and a deep thinker along these lines, recently delivered an address on this subject, and I am going to read you a few extracts, and this is not from a medical man, but from a doctor of philosophy:

> The democracy that is to endure will not only train the minds and the hands of its future citizens; it will look to the conditions of their bodies. Again I voice a platitude which must become a practice if we are to prove ourselves worthy of leadership among the nations of the earth. We have shamefully disregarded the physical well-being of our children. It is as vitally important to teach boys and girls how to take care of their bodies, the essentials of a

well regulated diet, the value of recreation and play, of sunshine and pure air, of rest and sleep, and the relation of these things to the training of the mind and the hand, to the development of character and to the preservation of life itself, as it is to teach them to read and write. The health of the nation, we have lately discovered, is of vital concern in its striking power. * * *

Health instruction should be given in every school room with the same regularity and definiteness that instruction is given in English or any other subject. The courses of instruction now given in physiology and hygiene should be revised by a competent group of physicians, social hygienists and teachers, and included in the curriculum of every elementary and secondary school in the state under the name of health instruction. The examination now improperly called medical inspection or examination or physical examination should be called health examination. Every child should look upon a health examination as a matter of course and not something unusual in school affairs. The child should expect a health examination just as he would expect his history or English examination. The term health should be emphasized in every way.

One of the most disastrous by-products of the world war has been the great increase in malnutrition among our children, and the present high cost of living deprives many children of sufficient and proper nourishment. I think probably the conservation of food during war time was rather a good thing for a number of us adults, but it worked permanent injury to a number of our growing children at that time. So the question of malnutrition in children has come to the fore, and the lay and medical press is filled with articles on this subject, and there are a number of welfare agencies who are devoting their entire attention and activities to this work.

Undernourishment and malnutrition affect both the physical and mental development of the child. A normal child is a properly nourished child, and nutrition must be considered one of the special factors, then, in favoring normal development and growth.

Last week you heard the last word on theories on nutrition, and Professor MacCullum has demonstrated very clearly the dietetic importance of his "fat soluble A" and his "water soluble B" in the nutrition and growth of animals, and this has a very direct and practical application to the dietetics of children.

There is an organization in New York City that was formed only eighteen months ago known as the Child Health Organization, and I think it is one of the most active and aggressive agencies we have today engaged in this line of work. Its objects as outlined in the literature of the association, are:

To teach health habits to children, and to secure adequate health examinations and health records for all children in the public schools of this country. To consider the urgent problem of malnutrition among school children. To safeguard the health of children in industry, and to cooperate with other bodies in securing an enlightened public opinion and legislation.

They have produced and distributed a vast amount of excellent literature, and have inaugurated a nation-wide propaganda for the periodic weighing and measuring of school children. This is necessary to determine the prevalence and extent of malnutrition. The index of nutrition is the ratio between the weight and height at a given age, and children who are more than seven per cent. under the average should be classed among the undernourished.

Malnutrition may accompany chronic organic disease, but much more frequently it is the result of insufficient and improper food, bad habits of eating, carious teeth, faulty health habits, such as lack of fresh air, sufficient sleep, and proper exercise. Ignorant and indulgent parents are chiefly to blame, although poverty as it affects the housing and living conditions is an underlying cause.

I suppose in your private practice you have the same experience that I have. A mother will bring her child and she will say, "This child will not eat, you cannot make him eat." It is an undernourished child, and when we delve into the history it is not difficult to determine the faulty habit that is the basis of this malnutrition. A record of the weights and heights of children in the orphan asylums in the State, comparing them with children outside of institutions, was recently made by the State Board of Charities and only a very small percentage of undernourishment and malnutrition was found in the orphan asylums. These children are obliged to live according to the rules of the institution, and are trained to practice health habits that are normal and natural. They go to bed early, eat proper food at proper hours, and do not eat between meals, and escape many things that enter into the lives of children that are at large and have indulgent parents. The result is that there is only a very small percentage of malnutrition among the institutional children in New York State.

One of the most effective methods in dealing with malnutrition is the nutrition class. Dr. Emerson of Boston, some eight or nine years ago, started a nutrition class of poorly nourished children, along the same lines as the tuberculosis class. This method is now being extensively adopted throughout the country. The undernourished children meet weekly to have a medical examination by a physician and are given simple class instruction in food values, health habits, and personal hygiene. The mothers are always urged to be present at these meetings.

Competition by placing the child making the largest weekly gain at the head of the class is a great stimulus. It secures the cooperation of the child, and in order to sit at the head of the class, he will drink more milk, and go to bed early, and live a healthy life, things which the parents perhaps have been trying in vain to have him do.

The average American family, unfortunately, is becoming smaller, and the children are becoming rarer and possibly more precious. So, from an economic point of view, the children constitute the nation's most valuable natural resource. Every effort to conserve and preserve the health and lives of children should receive a response from the members of the medical profession.

I have endeavored in a most superficial and incomplete manner, I fear, to outline the possibilities and the opportunities for service for physicians along the lines of social preventive pediatrics, for I believe that herein lies a factor of inestimable value in favoring the normal development of the child.

361 State Street.

THE RESPIRATORY TRACT AS A PORTAL OF ENTRY IN INFECTIOUS DISEASE.*

By IRVING WILSON VOORHEES, M.S., M.D.,

NEW YORK.

ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

THE problems of age, growth, and death are in the last analysis to be studied and interpreted in the light of bacterial infection. Explanations of the causes of disease which are mechanical or physical have receded further and further into the background *pari passu* with the advance of clinical microscopy. It is becoming more and more apparent that human efficiency, industrial or artistic or literary, is a matter of the general health of the individual, and that the general health is dependent upon the degree and extent to which the organism has suffered from invasion by bacteria.

Bacteriology and its companion science parasitology have advanced during the past two decades more rapidly than any other branches of medical science. Not more than fifteen years ago, books on bacteriology consisted of a few pages only, which described largely the technique to be followed by students in their work. To-day, a handbook consists of from 600 to 700 pages which deal not only with laboratory technique, but with the vital matter of infection and immunity, the effects of bacterial poisons, the phenomena of precipitation, chemotaxis, phagocytosis, serum enzymes, etc. Medical dictionaries are full of such terms as alexins, anaphylaxis, allergy, complement-fixation — terms which ten years ago were practically unheard of. These have all grown out of the new science of bacteriology which has led the investigator further and further afield into a study of the problems of life and death.

One by one these problems are being solved. For instance the mountain whites of Tennessee were known for years to have been shiftless, ignorant, lazy, economically worthless, of poor intelligence, indifferent to their immediate surroundings, having little or no interest in the outside world. Through the beneficent aid of a great philanthropist, a committee of investigation set to work and found that all the characteristics of these strange people were being influenced by the parasite known as hookworm, which was sapping their vitality, and it was found that by eradicating the hookworm the mountain whites could be brought into their own, and that under conditions of health they would show many qualities quite as desirable as those possessed by more fortunate neighbors.

In Africa, explorers were amazed by the lethargy of the inhabitants in certain regions who persisted in constant sleep, arousing themselves only in response to the need for sustenance which was of the simplest form and the most readily attainable. Other tribes would fish and hunt with avidity in order to secure subsistence; but these soporific people would not exert themselves in the least. Finally science solved the question by finding an insect, the tsetse fly, which was infected by an organism not pathogenic for its species but fatal to man when received into the blood stream by the hypodermic bite of the fly. Sleeping sickness is now classified as a curable disease as a result of bacteriological investigation.

A struggle for survival between bacteria and their toxins and the cells of the human body is going on incessantly. In truth "there is always a war in our members" which in the number of soldiers engaged makes the late war insignificant and contemptuous. Health, the vital principle of bliss, is under constant and continuous assault by bacterial invaders. Metchnikoff, the first great student of this human life struggle, thought that its solution must lay in the tremendous number of bacteria which live, thrive, and grow in the intestinal tract. He believed that most diseases would disappear, and that old age would be greatly retarded if we could keep the intestinal tract free from harmful bacteria. Hence the sour milk theory of sterilizing the intestine, which only a few short years ago had a considerable vogue, but which has apparently fallen quite largely into disuse at the present time. There is something pathetic about the gray-bearded old scientist going daily in and out of the Pasteur Institute with all the assurance of a man who has solved one of the most vital problems of existence, swallowing his daily portion of *Bacillus bulgaricus* and extolling its virtues, only to be cut down at what he considered the relatively youthful age of 71 years. (Metchnikoff died in 1916.)

Metchnikoff had a learned and worthy follower in Dr. Christian A. Herter of this city whose book on the "Common Bacterial Infections of the Digestive Tract" enjoyed a wide reading some ten years ago. Dr. Herter believed that life could be prolonged if the digestive tract could be rid of its unwelcome flora and he gave some excellent advice as to what might be tried in bringing this about.

Is it not strange, however, that neither the learned Metchnikoff nor his worthy disciples ever paid much attention to that other great tract which is in constant use during every breath we take while life lasts? Statistics show that more persons die of respiratory disease or some complication of respiratory disease than of all other infections combined. We have just been through a very graphic example of this fact in the recent influenza pandemic. It is going to be emphasized more and more that the majority of acute infectious diseases find a site of origin somewhere along the tortuous path of the airways.

Comparatively little has been written concerning the bacterial inhabitants of the respiratory path, but the recent study of "carriers" has served to emphasize that acute respiratory diseases which are looked upon as trivial do not always fully recover, and that an enormous number of people harbor infective bacteria which are harmful to themselves and are capable of starting a new infection on the membranes of susceptible subjects. This study of carriers began with diphtheria and typhoid, but was most successfully and brilliantly worked out in the vast amount of investigation into the origin and transmission of cerebrospinal fever.

A carrier is one who harbors pathogenic microorganisms in his body without exhibiting any manifestations of the disease. The diphtheria bacillus, the *B. typhosus*, the pneumococcus, streptococcus, meningococcus, and many others may exist in the

*Read in part before the New York County Medical Society, November, 1918.

nose and throat without giving any signs or symptoms of their presence. Physicians and nurses in the wards of hospitals frequently show these germs in pure culture in the nose and throat, but go about their work all unconscious of any danger. Such are termed *temporary* carriers; for once they are away from the locus of infection for a few days, the bacteria can no longer be found.* An *acute* carrier is one who has had a disease and who harbors the microorganisms throughout convalescence and for a few days thereafter; while a *chronic* carrier is one who has recovered from an infection, but carries the germ for months or years thereafter. The so-called "typhoid Mary" who set New York by the ears a few years ago, and who was responsible for the illness and death of several members of the staff at the Sloane Hospital is the most notorious example of a chronic carrier on record. This study of carriers has shed new light upon the spread of communicable diseases, and has emphasized the necessity of taking at least two negative cultures from all cases before they are discharged from quarantine. The difficulty of sterilizing either the respiratory or intestinal tract after an acute pathogenic infection is obvious, but it must be done if public health is to be safeguarded, and the newer teaching of medicine must demand and see that it is done.

"The cure of carriers is one of the pressing problems of preventive medicine," says Rosenau, "but one hopeful feature is that their number may be diminished by isolating and diminishing the cases. Thus, the number of typhoid carriers falls off sharply as a result of any successful measure directed against the clinical case." One of the great dangers is the "missed case," that is the mild and atypical instance which is not recognized. Such, for example, as walking typhoid and ambulant plague. All of the exanthemata may be so mild as to defy detection. These mild cases go to school, ride in the tramways, attend public lectures, etc., while feeling not quite up to normal, but not ill, and they are probably the greatest agents in provoking the serious spread of disease in others.

This carrier question came out into the light very prominently in the first weeks that America was at war with Germany, because of the development of cerebrospinal fever in the cantonments. Great Britain had already been through this phase of her troubles, and her experience was of material aid to this country in determining what course to pursue in checking the inflow of meningitis from civilian life. Insofar as I know we have not as yet published an official report of our findings here in America, but in 1917 the British Commission made its report under the title "Bacteriological Studies in Pathogenicity and Preventive Control of Cerebrospinal Fever among the Forces during 1915-1916." It was found that the nose, and especially the nasopharynx, was a frequent site for the meningococcus, which, like the pneumococcus, could be classified under four different types by means of bacteriological tests. Diagnosis was made by the presence of an epidemic type of meningococcus in the nasopharynx, together with clinical evidences of meningitis and the presence of Gram-negative cocci in the spinal fluid. At first some difficulty was experienced in getting uncontaminated cultures of the flora of the nasopharynx, but Dr. C. E. West succeeded in contriving a covering tube which protected the swab from being contaminated in the mouth. Swabbing of the nasopharynx was always done simultaneously with lumbar puncture, and the culture was grown on a medium designated as "nasgar." It was found that the meningococcus does not grow below a temperature of 25° C. nor above 65° C., but does best at about 37° C. Prof. F. W. Andrews and Captain Flack reported that "in every instance in which the cerebrospinal fluid was positive, the same type of meningococcus was present in the nasopharyngeal secretion." And they conclude that every case of cerebrospinal fever is an instance of a carrier developing the disease. By culturing the nasopharynx, these cases can be recognized within 48 hours.

Some cases of meningismus were observed. These patients suffered from severe headache, pain in the nape of the neck, backache, a slight Kernig, with a temperature of from 100° to 102° F. The meningococcus was frequently found in the nasopharynx, but in a few hours the symptoms would all subside and the patient appeared quite well again. Nothing is said in this report as to the spinal fluid in these cases, nor as to the length of time required before the nasal cultures were negative for meningococcus. One occasionally sees similar symptoms in influenza without the presence of meningococcus in the nasopharynx. The complications of meningitis as noted by the British observers were arthritis, hydrocephalus, and in a few cases total deafness coming on within twenty-four to forty-eight hours.

In doing lumbar puncture general anesthesia was used to relax the muscles, and because an anesthetic increases intraspinal pressure making it possible to withdraw from 70 to 100 c.c. at a sitting.

A number of antiseptics were tried in an effort to sterilize the nasopharynx and such other part of the respiratory tract as seemed to be involved. For instance, spraying the nasopharynx with 1 per cent. formalin once a day. Washing the nasopharynx with 0.1 per cent. potassium permanganate. Washing same with chlorine water, the formula of which is potassium chlorate 10 grains, strong hydrochloric acid two minims, and water to one ounce. A spray of iodine and menthol was used. Also a preparation called "eusol"; and, finally, chloramine solution, which latter is set down as being "most efficacious."

It was found, as one might have suspected, that the use of strong irritating antiseptics is contraindicated. The formalin solution was actually harmful. Chloramine solution was used twice a day "snuffed up out of the hand," a procedure which is against all the rules of otolaryngological practice.

Some success was attained with serums, but the authors say that commercial serums were disappointing. The best serum was supplied from the Millbank-Lister Institute. This serum may have been effective because it increases phagocytosis. Thirty c.c. were given initially followed at twenty-four hour intervals by a second and third injection. Out of 33 cases thus treated only 3 died (9.09 per cent.), but unless given by the third day of the disease or earlier no good effect was seen.

*Even the cholera vibrio and hookworm may dwell in the intestinal canal without any manifestation of disease and the *Plasmodium malariæ* may exist in the blood and spleen without "malaria."

Since the meningococcus is one of the least resistant of all pathogenic bacteria and can be destroyed *in vitro* by mild antiseptics, it seemed strange to the authors that this was so difficult to carry out clinically. In some patients a negative culture was obtained and in a few days the culture taken was again positive. This was due either to the propagation of bacteria in the recesses of the pharyngeal vault, or to their emergence from the submucosa, or possibly to poor technique in the application of the antiseptic to the mucous membrane. Finally a method of vaporizing the respiratory tract was hit upon which proved quite successful. An apparatus known as the Lingner spray outfit designed for room disinfection was adapted to the spraying of steam carrying also an aqueous solution of chloramine. It was found that this spray when directed against a staphylococcus plate killed the staphylococci immediately if used as a one and one-half per cent. solution; and as a two per cent. solution at a distance of five feet all bacteria were killed within five minutes. This apparatus is in use at the Rockefeller Institute, New York, but it is cumbersome, raises the temperature of the room about 20°, and cannot be turned on and shut off promptly. Such a massive contrivance is not at all necessary, for the nasopharynx is very easily medicated by a simple method, to be described later on in this paper.

At this point it is sufficient to emphasize the fact that most agents used for destruction of the meningococcus in the respiratory tract were disappointing, with the single exception of chloramine. To quote from the report of the British Commission: "The successful results obtained with chloramine are more than encouraging, and indicate that a large proportion of chronic carriers can be definitely freed of the meningococcus in a short space of time."

The exanthemata are all interesting examples of genuine nose and throat infections which are localized for a very short time only and then become constitutional diseases with well marked and definite symptoms upon which the diagnosis is made. Perhaps this group might well be called enanthemata because the first manifestations are seen on the respiratory mucous membrane. (Koplik's spots, the strawberry tongue, etc.) There has been much discussion as to the mode of communicability. For a long time it was thought that the virus of these diseases was air-borne over considerable distances, but it is now well understood that close contact with some one having such an infection is necessary to its acquirement. Only two diseases, smallpox and measles, are capable of being carried any distance on currents of air; all others are transmitted through contact with fingers or utensils or are breathed in directly by a contact of ten feet or less. At the Pasteur Institute for infectious diseases in Paris, separate wards open into a common hall and nurses and attendants pass freely from one to the other. In two and one-half years, out of 2,000 patients suffering from smallpox, measles, diphtheria, erysipelas, scarlet fever, and sore throat of unknown origin, there were only six cross infections; namely, four of smallpox and two of erysipelas. The same has held good at the children's hospital in Paris (Hôpital des Enfants Malades). Spraying of indoor air by coughing, sneezing, and the like pollutes it with disease germs which find ready lodgment on the mucous membranes of those living in the same room, but where the ventilation is good and the air well diluted the danger is very much diminished. In the latter instance the hands are probably more responsible than the air for passing the disease germs along.

Of the exanthemata, scarlet fever is the type which deserves most study because of its complications and the well-marked characteristics upon which a diagnosis is based.

Like all other diseases of this group, the radius of infection in scarlet fever is fairly limited to the distance which droplets bearing the virus can be carried. If the cause of scarlet fever is a streptococcus, as seems to be the consensus of opinion at this time, it can persist in dwellings, upon toys, etc., for many weeks, and may settle down from infected air upon furnishings which are capable of infecting non-immune persons long after the original focus has been forgotten. Very often scarlet fever begins with a sort throat,—the pharynx is congested and plaques may be seen on the tonsils resembling specific condylomata or having the look of the mucous membrane after an application of silver nitrate. This appearance may be quite transitory, may persist throughout the course of the disease, or may disappear and then recur. Occasionally "cheesy" spots appear on the tonsils as in a follicular tonsillitis. One can produce symptoms resembling scarlet fever by swabbing a monkey's throat with secretion from the throat of a scarlet fever patient. An organism known as the *Streptococcus scarlatinæ* has been found in the nose and throat, and on the tonsils and tongue. According to Mallory it is "a protozoon-like body." The nasal mucous membrane is red and sometimes bleeds slightly. From it and from the nasopharynx a streptococcus is rather constantly obtained which explains the large number of patients who contract middle ear and mastoid infections. The virus also circulates in the blood. Severe forms of scarlet fever may cause ulceration and necrosis in the nose with invasion of the sinuses, the orbits, or deep-lying structures such as the ascending pharyngeal artery. This is rare, and if it does occur, is not likely to appear before the twentieth day.

Milk outbreaks may be very extensive, and may defy detection until the milk is studied bacteriologically. In this respect scarlet fever resembles so-called "streptococcus sore throat."

It would seem that much could be done to shorten the course of scarlet fever by trying to cut off the foci of infection in the nose and throat. Cultures are especially desirable at intervals during quarantine, and McCollom of Boston City Hospital does not release any patient who shows discharge from the nose or throat or other signs of germ activity. The quarantine period is fifty days or more, and no patient should be released who has an active otorrhea, rhinorrhea, or discharging abscesses.

Serum treatment of scarlet fever was first used in Russia. Three injections of an autogenous vaccine made from the bacteria infesting the nasopharynx or tonsils were given with the following results: Of 285 cases having only one injection, five developed scarlet; of 148 cases receiving two in-

jections, two came down; and of 22 cases receiving three injections none were attacked with scarlet. Just how much these figures mean must be left to time to decide, but the vaccine treatment when supplemented by sterilization of the nose and throat is at least worth trying.

Measles is one of the most pronounced of the exanthemata in its manifestations of nose and throat signs. It is ushered in with a discharge from the nose which is apparently a simple acute rhinitis, and in a few hours the well-known Koplik spots are seen on the mucous membrane of the mouth. Anderson and Goldberger have made extensive studies in the bacteriology of measles, but have not identified a specific germ. Nevertheless a virus found by them in the nose and throat resists drying for 25 hours, and freezing for 25½ hours. When heated to 15° C. for 24 hours it is still virulent; but heated to 55° C. for fifteen minutes it is killed. Hektoen found this virus in the blood 24 hours before any eruption, and it persisted for 25 hours after eruption. As is true of all other diseases the exfoliating skin is not infective, the danger period being at the incubation time during the pre-eruptive stage lasting about 9 to 11 days. Recent researches of Ruth Tunnicliff, pathologist, indicate that a bacillus is the cause. Infection cannot be carried from a case of measles after the secretions are free from the causative germ. Dr. Chapin has said that isolation in measles has been a failure and he is right, for when diagnosis is made from the eruption, the chance of communicability is at a low point, even the secretions being only slightly infective at that time. We cannot hope to do much in the prevention of measles unless we can make the diagnosis early and isolate the case during incubation. At this time, that is early in the disease, it is possible so to sterilize the nose and throat that communicability is reduced to a vanishing point.

Diphtheria is probably the best example we have of a genuine infection of the respiratory mucous membrane which refuses to remain localized and rapidly produces constitutional symptoms and complications of severe degree. The diphtheria bacilli almost always enter the body by way of the nose, throat or larynx, where they set up distinctive and severe reactions. Kissing, coughing, shouting and vigorous conversation eject droplets from the mouth laden with diphtheria bacilli which find ready lodgment in nonimmune persons. In this way the causative agent is distributed to fingers, food, toys, handkerchiefs, etc. Food, especially milk, is likely to be contaminated by coughed-up bacteria which settle into it from the air, and also by the contaminated bands of workers. As mentioned above, the early studies concerning carriers were worked out with diphtheria. Of families having one case of diphtheria, 66 per cent. of the healthy members showed living diphtheria bacilli in the nose or throat; while among attendants on diphtheria patients, 37 per cent. gave positive cultures when in apparent health. In a Boston school having 4,500 pupils, all in good health, and in the absence of any diphtheria epidemic, one per cent. had positive diphtheria cultures. The most virulent diphtheria bacilli studied by Dr. Park came from a patient having a "mild tonsillitis" All this in spite of the fact that the bacillus dies readily in the presence of light and air. In the throat, however, it may persist anywhere from three days to nine weeks after the disappearance of all diphtheritic membrane. Diphtheria bacilli are much more easily destroyed than bacillus typhosus, but when protected by mucus secretions under conditions of warmth and moisture, and in the absence of direct sunlight and air they may live for months. For this reason many patients coming to the throat specialist complaining of a slight catarrh or other apparently trifling symptoms are overlooked unless it becomes a routine habit to culture every new case. I have personally discovered diphtheria bacilli in the nose in cases of mild rhinorrhea without any apparent reason for the symptoms complained of. Any worker in the field of rhinology will feel amply repaid for the trouble of taking cultures in patients who come for the first time, or repeated cultures in those who are not doing well under ordinary treatment. If no cultures are taken from the nose, prevention fails its purpose. There should be no release from quarantine until at least two negative cultures from both the nose and throat have been taken at 48-hour intervals.

Whooping cough is looked upon by the laity as a mild infection, and yet in England and Wales during 1891 there were more deaths from it than from measles, diphtheria, scarlet fever and typhoid combined. The cause is a small bacillus which inhabits the lower respiratory tract, chiefly the trachea and bronchi. It was first described by Bordet and Gengou in 1906. This bacillus probably enters the lower tract by way of the mouth and nose, causing no symptoms there, but creating much irritation below the vocal cords where conditions are best suited for its propagation. This irritation is so intense that the mucous glands throw off an enormous amount of sticky, slimy exudate in which the bacillus is concealed associated with many leucocytes. Dogs and cats are quite susceptible to it. If one drop a little of this whooping cough secretion into a puppy's nose the infection will be caught up by all other dogs associated in the same kennel with the puppy. Like many other infections, whooping cough is most communicable during the early stage. Later on the bacilli coughed out die quite quickly in the sunlight. It should be possible to kill most of the bacilli *in situ* by direct application of antiseptics to the tracheal and bronchial mucous membrane. Poor mothers on the East Side of New York have long advocated the gas house cure for this malady, and it is just likely that the gas inhaled may destroy the Bordet-Gengou bacilli provided that it does not first destroy the baby.

Parotitis is another infection which travels in through the mouth and enters the parotid gland by way of Stenson's duct. The virus of mumps, whatever it is, has a special selective action on glands of the racemose type. Just how it reaches the testicles giving rise to a complicating orchitis has never been explained.

One of the most striking examples of an airborne infection carried by excretions from the respiratory tract is afforded by pulmonary tuberculosis. Strange to say, tuberculosis of the upper respiratory tract is quite rare, and when it occurs is secondary to advanced infection lower down. Primary tuberculosis probably never occurs in the nose, al-

though it is quite likely that the nasal mucous membrane harbors tubercle bacilli for at least a short time, or until they work their way down into the bronchi and lungs on the inflow of air passing through the nose. Tuberculosis is an infection which spreads from human to human through association of the well with the ill, and usually by way of the air tract, although it is sometimes taken in with food and drink, especially milk.

Cornet performed an interesting experiment. He infected a carpet with tuberculous sputum, allowed it to dry and then confined 48 guinea pigs in the room while the carpet was being swept. Out of the 48 pigs, 47 developed tuberculosis, which was confirmed at autopsy. Such experimental evidence has shown that only a few tubercle bacilli are required to produce respiratory infection; while a much greater number is needed to infect the intestine.

Clinically, the bovine bacillus seems to be the one most commonly affecting the respiratory tract, and this quite often by way of the tonsils. Tuberculosis of a tonsil is by no means rare, as has been proven by G. B. Wood of Philadelphia and others. Pulmonary tuberculosis not uncommonly begins with "a cold" which does not recover promptly. The patient remembers having coughed and raised a quantity of yellowish sputum for some weeks, which did not improve under home treatment or the ingestion of cough mixtures. When such a "cold" is associated with persistent laryngitis, tuberculosis of the larynx often supervenes, and it seems not unlikely that the tuberculous process began in the larynx and lungs almost simultaneously.

The tubercle bacillus is difficult to kill because it has a very fine enveloping capsule which resists staining as well as the influence of many if not most antiseptics used *in vivo*. Through daily local antiseptic treatment, the bacilli may, however, be greatly reduced in number and thus give the resisting elements of the body a better chance to overcome the infection.

A disease in many respects analogous to tuberculosis is leprosy. Leprosy is caused by the bacillus lepra, which was discovered by Armauer Hansen in 1874. This closely resembles the tubercle bacillus, but grows with difficulty on culture media and is scarcely pathogenic for lower animals. There is still some question as to the portal of entry, but evidence is increasing which seems to show that the bacillus lepra may find its way through the mucous membrane of the nose and throat without leaving any ulceration or other sign of its passage. In 1897 Sticker enthusiastically stated such to be the case when speaking before the International Leper Conference, and declared that the nasal secretions are dangerous. *Bacillus lepræ* has been found in nearly all tissues and organs of the body—upon the mucous membranes, in the skin, spleen, liver, and testicles; but, strange to say, not in the sputum. Jeanselme, Laurans, Gerber, Werner, Sheroux, and others have shown that the bacillus of leprosy is frequently found in the nasal secretions, even in the early stages of the disease. It is possible that besides being inhaled, the bacillus finds its way to the nose by way of the fingers. There is never any local lesion in the nose in the incipient stage, but very often the nose is involved at a later stage manifested by marked macroscopic lesions.

Before passing on to "common colds," influenza, and pneumonia, a few words should be said concerning lowered resistance in its relation to infection. The action of drafts on colds has always been emphasized by the laity. Not only rhinitis but many other infections, notably pneumonia and rheumatism, may follow chilling of the body or wet feet. Bacteria are already present in the respiratory tract and become active just so soon as the general body resistance falls below normal, unless, of course, there are already present in the system sufficient factors of safety to offset even an overwhelming number of bacteria. Emery says that when the surface of the body is chilled the phagocytes circulating through the skin are alternately subjected to excessive interior warmth and excessive exterior cold which renders them less efficient functionally. He found that immunity is a purely relative term, and that susceptibility may be superinduced by experimental means. For instance, "Fowls are immune to anthrax, but are rendered susceptible to it if kept for some time standing in cold water."

Cold and wet are much less likely to produce disease during muscular exercise, but fatigue must be avoided. Exercise increases the heat of the body, increases heart action, accelerates the movement of blood through the skin, and raises the internal temperature of the body; therefore, the temperature of the leucocytes never falls much below normal and their function is not reduced.

A new factor favorable to bacterial infection is found in the recent work on "acidosis." Normally the blood is alkaline. When this alkalinity is reduced the action of antibodies is lessened and germs and their toxins find a *status optimus* for growth and activation. Alexins and opsonins work best in an alkaline medium; therefore, clinically something can be done in the matter of diet to favor alkalinity. Ingestion of acid fruits converts them into tartrates, citrates, and the like, which are, of course, alkaline by the time they reach the blood. This may explain the great faith of the laity in the use of lemons during acute illnesses, and in the light of recent studies this faith may have a foundation in fact.

It is now fairly conceded that colds are infectious, that they are extremely communicable, and are passed on from one person to another. Rosenau says, "Could the sum total of suffering, inconvenience, sequelæ, and economic loss resulting from common colds be obtained, it would at once promote these infections from the rank of the trivial into the rank of serious diseases." Predisposing factors are chilling of the body surface, exposure, and fatigue; the exciting factors are bacteria which grow on the mucous membrane and bring about constitutional effects through their absorption or through the activity of their toxins in the circulating blood. It is a curious fact that in the frozen north explorers say that there is no such thing as colds in the head, chest, etc., but that as soon as the men return to civilization these troubles begin, which seems to prove that bacteria either are not present in quantity or do not act in the extreme cold of the polar regions. Could colds be prevented there would hardly be such a thing as rheumatic fever, sinusitis, pneumonia, influenza, and a host of airborne diseases. Acute otitis media would disappear

and mastoiditis by way of the Eustachian tube would be a thing unknown. All this means that if one could keep the upper respiratory tract even relatively sterile, many of the plagues which now beset mankind would vanish from the earth.

Of these plagues we have had recently one of the worst epidemics of influenza in the memory of man. In 1889 and 1890 influenza spread to the four quarters of the globe, traveling from east to west in a wild hurricane of death and disaster. Pfeiffer in 1892 discovered a bacillus which he thought to be the cause of influenza, but this has not been well recognized in the present epidemic; for in many cases of clinical influenza it has not been found at all, and we have fallen back upon the convenient "filterable virus" theory for an explanation of the ravages of the disease. It is estimated by the Public Health Bureau that the mortality from influenza for the nine weeks' period ended November 9, 1918, was nearly double that in the American Expeditionary Force from the time the contingent landed until the cessation of hostilities. "In general," says the report, "the epidemic traveled from east to west. In a number of Eastern cities, notably Boston, where the greatest mortality occurred during the week ended October 5, the largest number of deaths were reported for earlier periods than that which covered the height of the epidemic for the forty-six cities taken as a group. For the entire nine weeks' period the greatest mortality due to the epidemic according to population—7.4 per 1,000—occurred in Philadelphia, and the next greatest—6.7 per 1,000—was reported for Baltimore." The fatalities in 46 cities totaled 82,306, while the toll taken by the grim reaper in the cantonments may finally be seen to equal the number of deaths on the field of battle.

The bacillus, whatever it is, is kept alive in carriers; for, in Boston, in the absence of any epidemic whatever, from 25 to 55 per cent. of all patients having cough and expectoration showed the influenza bacillus as described by Pfeiffer.

Many observers have reported a leucopenia in this epidemic which probably accounts for the poor resistance shown by many patients once the infection got under way. There was also an acidosis, indicating that the blood was poor in antibodies. Immunity is probably slight, although some observers say that few persons who suffered from the disease in 1891 were attacked during the present epidemic. This may be rather a matter of age incidence than actual acquired immunity, for in some cases at least it has seemed that any number of attacks have been suffered. We must not forget, however, that in the presence of an epidemic almost every ache and pain is diagnosed as influenza, when in fact many minor ills are not even remotely related to that disease.

The influenza of 1918 was remarkable for the number of cases complicated by pneumonia, many of them fatal within a few hours. The pneumococcus is, as we know, a constant inhabitant of the upper airways, although it is found, too, in the sputum during an ordinary bronchitis. It lives readily on all mucous membranes and grows in the blood stream. In spite of this fact, however, the pneumococcus is frail, being readily destroyed by heat at 52° C. within ten minutes. But it resists freezing, and will live for months in dried sputum.

Pneumonia might be well studied in terms of anaphylaxis, the crisis resembling anaphylactic phenomena quite closely. No immunity is possible, for the pneumococcus acts too quickly for the formation of antibodies, and the patient is either better or dead before his friends realize what has happened to him. One attack predisposes, and it is possible that the trachea and lungs are never quite freed from the invader even after apparently complete convalescence.

It is possible here to say only a few words about the *focal infections* which, in the nature of the case, are chronic. Dr. J. B. Murphy was among the first to study diseases of focal origin, and curiously enough he succumbed to aortic disease which was said to have found focal origin in a frontal sinus. Dr. Mackenty of New York has studied many cases of sinusitis in their relation to general disease, and he will doubtless have something to say on this topic in the discussion of this paper.

The tonsils have already been mentioned as portals of entry for rheumatism and tuberculosis. Probably many other chronic diseases will be found in time to trace their origin to focal infection in the tonsils.

Teeth for purposes of convenience may be looked upon as closely associated with the respiratory tract. Their importance as foci in chronic arthritis has been recorded by many observers within the past six years. Abscesses occur in the root canals and in the tooth sockets from which bacterial poisons are constantly being absorbed into the system.

The trachea and lungs are usually recognized as manifesting symptoms of disease peculiar to themselves; but many disorders of widely remote organs such as the gall bladder, kidneys, and intestine are associated with the expectoration of foul pus. It should be emphasized that wherever pus is found in the body the site is very likely a source of constant absorption which may lead to such a complication of diseases that it is impossible to say which was primary and which secondary. No physician should be satisfied with a sputum report which declares that "no tubercle bacilli were found." Many other germs quite as important are completely overlooked on the assumption that "it is always a mixed infection, anyway." It is possible to rid many chronic "carriers" of streptococcus, staphylococcus, etc., and it should be the rule in all chronic cases to begin the preparation of an autogenous vaccine from the germs found. Vaccine alone will not cure the case, but it may prove of material aid when combined with local treatment.

Treatment of Infections of the Respiratory Tract.—The principles of treatment are in every case about as follows: (1) Take a culture, preferably on nutrient or blood agar. (2) Open the nose by means of astringents. (3) Apply from a pint to a quart of irrigating fluid. (4) Drop or spray in a sufficient quantity of a non-irritating antiseptic to kill the bacteria causing the infection. (5) Repeat this procedure twice a day, or, if the need be urgent, every two hours. Chronic cases may be limited to one treatment daily.

These principles vary only in detail according to whether one is working in the nose, larynx, or bronchi.

As to the culture, one must be sure that no anti-

septic has been applied to the nose for at least three hours before taking. If this rule is ignored either no culture can be grown or the germs are so reduced in vitality as to make the preparation of a vaccine impossible. The ordinary sterile cotton swab is employed, but care must be taken to see that in the making not too much cotton was used or otherwise a vestibular culture will be taken and no contact will be made far up within the nasal fossæ. A postnasal swab should also be used at the same sitting, and I feel that we are under some obligation to Dr. C. E. West, the English physician who devised this very simple and practical way of making postnasal cultures.

To open the nose it is well to combine an astringent with an anesthetic because the medication to be used later on often smarts considerably. Cocaine solution 2 per cent. with five drops of adrenalin to the ounce makes a satisfactory spray and opens the nose, if there is not too much swelling, within a few minutes.

Nasal irrigation has long been condemned by aurists because many cases of middle ear and mastoid infection have followed the carrying into the Eustachian tube of germ-laden mucus. It is not safe as a rule to permit patients to irrigate at home for the reason that they often do it so badly that nothing is accomplished, or they blow the nose and force any infection that may be present in the nasopharynx into the Eustachian tubes. In his office the physician may use an ear syringe, or the douche combined with siphonage devised by Mr. H. B. Nichols. The latter is eminently safe as no water can remain in the nose under ordinary circumstances if the syphon is working properly. In any case it is very important that the patient does not blow the nose. The only thing allowed is to pull back the air through the nostrils into the nasopharynx. In this way any fluid which clings to the Eustachian tube will be drawn down and expectorated. As to the solution, nothing is better than physiological salt solution at body temperature. If very warm, the solution may burn the delicate surface epithelium and do more harm than good. Or if too salty there is a sort of cooking of the surface, and to this may be added anosmia or loss of the sense of smell. If preferred, the physician may use a bland alkaline solution, but he must be sure that it is isotonic.

The successful use of any antiseptic in the airways is based upon rigid adherence to the following principles: (1) The antiseptic must be strongly bactericidal for all germs which are likely to infest the airways. (2) The antiseptic must not injure the mucous membranes through its activity or in the mechanics of its application. (3) There must be thorough contact with all infected parts, and care must be taken to see that the antiseptic is not vitiated by dilution with excessive mucous membrane secretions. (4) Concentration of the antiseptic must be sufficient but not excessive in amount. (5) All conditions necessary to thorough bactericidal effect must be maintained over a sufficient period of time.

Many of the nasal antiseptics in use heretofore have done more harm than good unless all of the above desiderata were very strictly enjoined. For obvious reasons ideal conditions obtained only in the most careful hands where scientific exactions could be met; and therefore respiratory antisepsis has failed, although, considering the frailty of the invader in most cases, it should have succeeded notably well.

Some antiseptics commonly used in the respiratory tract are: Argyrol 5 to 25 per cent.; Silvol, an analogue of the silver salts, 5 per cent.; or silver nitrate, 2 per cent. in a DeVilbiss atomizer No. 52 fitted with a hard rubber bottle stem so that no corrosion of metal in the bottle will take place when not in use. If care is taken to clean these atomizers after each usage they will last a long time without being renewed. Protargol may be used in the same strength as argyrol. Both of these give better service if dropped into the nose with a medicine dropper, about five drops in each nostril. I have also used menthol in oil from 5 to 25 per cent. with good results in cases which were not too severe in type.

While these are all helpful, nothing has proved so efficient in practically all the varying types of cases as dichloramine-T made up as a 2 per cent. solution in chlorcosane oil. It is important in making the solution that as little heat as possible be used in dissolving the powder in the oil, and that every effort be made not to contaminate either the bottle or the drugs. No water must be used to wash the bottle, but ether or alcohol may be used if allowed to evaporate thoroughly so that the inside of the bottle is thoroughly dry. Only dark bottles should be used as the solution is greatly affected by both heat and light. A small quantity, say one-half ounce, should be made up so that there will be no waste in throwing away an amount of the spoiled solution. If possible it is much better to have the dichloramine-T fresh every day, and if one lives near a druggist he can have a fresh supply delivered to him each morning. The druggist weighs out the exact amount necessary for a 1 or 2 per cent. solution, warms it in the oil over a water bath allowing it to remain only long enough for complete solution, and then bottles it in a glass-stoppered amber bottle. For this purpose empty adrenalin bottles are very good as the pasteboard carton keeps out the light. These matters are gone into in detail because I feel quite sure that poor results, marked symptoms of irritation, etc., are due to faulty technique either in the preparation of the solution or the way in which it is handled afterward. The great advantage of dichloramine-T is that it is destructive to bacteria but not to animal tissue. This applies especially to the oily solution but not to the aqueous, which has not proved very satisfactory in my hands. Chlorcosane is an oil which is saturated with chlorine; hence it does not take any of the chlorine value out of the dichloramine powder for which it is a solvent. It is unnecessary to go into the experiments made by Dunham and Dakin to prove the antiseptic value of dichloramine as these have been published in many journals.

In medicating the nasopharynx the patient lies down on a couch with the head extended far over and hanging freely as in the position of operation for cleft palate. This makes the nasopharynx dependent so that any fluid dropped into it will remain as if in a basin. A thin glass pipette 16 cm. long by one-half cm. in diameter carrying a rubber suc-

tion cap like an ordinary medicine dropper is passed directly backward hugging the floor of the nose as closely as possible, and about one c.c. of the dichloramine-T in oil, made as described above, is dropped into the nasopharynx, the patient remaining in this position as long as he comfortably can. When he sits up, the excess fluid can be expectorated. In this way we medicate not only the nasopharynx, but the posterior ethmoid cells and the posterior pharyngeal wall. It is possible that some of the solution reaches the sphenoid as well. In carriers, such as the meningococcus carriers, for example, this performance should be gone through twice a day for two days when cultures should be made once a day thereafter until we are sure that the pharynx is practically sterile.

In medicating the larynx, the solution is sprayed in with a DeVilbiss atomizer, No. 18 or No. 52. The patient may be mildly cocainized if necessary with a 2 per cent cocaine spray. He is then asked to exhale, and when the the lungs seem empty the order to inhale deeply through the mouth is given and in this way the dichloramine spray is drawn down into the trachea. If one desires to make deep injections into the trachea, the well-known intratracheal syringe is used, and while the patient's vocal cords swing widely apart during inhalation, about one-half c.c. is dropped through the rima glottidis into the trachea. This is quickly followed by coughing, but enough of the solution remains to make antisepsis effective, as can be determined by taking cultures. By using one c.c., or even more if desirable, and asking the patient to turn quickly to the right or left side, we can medicate the right or left bronchus through the action of gravity.

When patients are too ill to sit up in bed, or where the difficulty of getting medication down past the vocal cords because of gagging or spasm of the glottis or inability to secure a view by the indirect method, that is, by use of the laryngeal mirror, is fairly impossible, one may inject the medication directly into the lumen of the trachea with a hypodermic syringe. The site of election is the cricothyroid membrane directly in the middle line, or, if this be difficult to determine, then one may introduce the needle just below the cricoid, between it and the first tracheal ring. A five-eighths inch hypodermic needle mounted on a 2 c.c. all-glass syringe is to be preferred. The needle is passed directly in at right angles to the vertical and in the plane of the middle line. About five minims of a 10 per cent. cocaine solution is then injected to anesthetize partially the tracheal mucous membrane. Coughing is likely to follow this step, and the barrel of the syringe is removed to give greater amplitude for this effort, but the needle is held in place to obviate another puncture. When the patient is quieter, the barrel containing from one-half c.c. to one c.c. of the medication is attached to the needle and introduction of the fluid into the lumen of the trachea takes place. In using the route between the cricoid and first ring of the trachea one must be careful not to inject into the posterior wall of the trachea instead of into the lumen, as intended. Some of the medication will, of course, be coughed out, but enough will remain to be effective for at least two hours, when the procedure may be repeated. If a heavy oil is used such as the chlorcosane which is a vehicle for dichloramine-T, one must have a wider gauge needle than would be otherwise necessary.

Regarding the use of dichloramine-T as a prophylactic, my personal experience has not been large, but during the influenza epidemic no patient developed the disease who received daily treatments with this preparation either at his own hands or mine. Lieut. Col. W. H. Haskins who has been doing nose, throat, and ear work at West Point ever since America went into the war, told me that he used dichloramine-T, 2 per cent. in spray form twice a day on about 400 cases who came into the service from civilian life from all over the United States, and that not a single case came down with influenza, although it was present among the soldiers at West Point not so treated in about the same proportion as elsewhere in the cantonments. Col. Haskins placed his patients with the head dependent as already described, and sprayed the solution into the nares so that it could run into the postnasal space, Dr. J. G. Dwyer, pathologist to the Manhattan Eye, Ear, and Throat Hospital, reports that he was able to clear up the meningococcus in some 32 carriers out of 35. The three which remained positive had some focus of infection which could not be easily reached by the dichloramine-T.

In conclusion I wish to say that at the present moment it would seem that this war has accomplished no greater or finer thing for humanity than the additions to medical science which have grown up out of the necessity of the horrors of the moment. Surgery has had its triumphs and our surgical literature is about to be enriched with a wonderful detail of knowledge gained at the bedside of those who have so nobly suffered in their country's service. But nonsurgical procedures are having their triumphs, too, and if we are not greatly deceived the sterilization of the respiratory tract by the use of the synthetic dichloramine-T in chlorcosane oil is one of the most important additions to a knowledge of the treatment of infections of the respiratory mucous membrane which up to the present time has been brought to light.

MALINGERING IN RELATION TO WAR NEUROPSYCHIATRIC CONDITIONS, ESPECIALLY HYSTERIA.

A CRITICISM.

By JOHN F. W. MEAGHER, M.D.,

BROOKLYN, NEW YORK.

FORMERLY MAJOR, M.C., U.S.A.; NEUROPSYCHIATRIST, U.S.A. BASE HOSPITAL NO. 37, ENGLAND; U.S.A. BASE HOSPITAL NO. 214, FRANCE; U.S.A. GENERAL HOSPITAL NO. 30, FOR PSYCHONEUROSES, PLATTSBURG, N. Y.; CLINICAL ASSISTANT, THIRD DIVISION, NEW YORK NEUROLOGICAL INSTITUTE; ATTENDING NEUROLOGIST, ST. MARY'S HOSPITAL, BROOKLYN, N. Y.

If one reviews the literature on this subject he will notice a marked difference of opinion as to what constitutes malingering, and as to its frequency. The reasons for the discrepancies are numerous. The most important ones relate to the doubt as to what malingering really is, and vary because of the different attitudes and training of the various observers.

In this discussion we will confine our attention

to malingering in its relation to neuropsychiatric conditions, and especially to hysteria. We will not speak of "shell-shock" cases, but will refer to the proper neuroses included under that indefinite and misleading term.

There is no one subject which has attracted more attention, not only among members of the profession, but by the public, than the question of malingering, especially in the various neuroses of war. This interest is centered especially on cases of hysteria.

In order that the subject be fully understood, one must at the very beginning state what is meant by malingering. For strange as it may seem, there is a great difference of opinion as to what really constitutes simulation. There is only one real definition; malingering means feigning illness. So we include under the term not only the feigning of symptoms or syndromes, but the utilization by the patient of present trivial symptoms for selfish ends, and the exaggeration of symptoms which are present for the same purpose. Where the patient consciously does any of these things, he is malingering; of this there can be no doubt.

A most important point to consider is whether a patient must be conscious, *i. e.* aware of what he is doing or not, to constitute malingering. Personally, I think his motive or motives must be conscious to charge him with being a malingerer. For this reason the expression "subconscious malingerer" is a faulty one, for it implies two different and opposed ideas, first, that he feigns illness, and secondly that he is not aware of doing so, which is a ridiculous conception.

It is just over this very point that so many observers clash. But I find that among the leading students of psychopathological phenomena this difference of conception does not exist. The difference of opinion is noticeable especially in gathering the opinions of numerous psychopathologists, neurologists, and other medical observers.

For a man to be thoroughly expert and capable of differentiating cases of doubtful hysteria and malingering, certain things are necessary:

1. The physician should have had a thorough training in abnormal psychology and analytical interpretation. And yet in culling the literature one sees very dogmatic opinions given by men who evidently do not even know normal psychology.

2. The physician must have an open mind. If he begins with the prejudice that all hysterics are malingerers he does little credit to the profession, and none to some of his patients. The study of each case must be individualistic.

3. In judging a particular case it does not clarify matters merely to dispose of that case by speaking vaguely of psychopaths, or the influence of suggestion, or for the writer to state that he does not believe in subconscious motives, etc. Let us stick to one point. We know there is such a thing as malingering; but it is not fair to say that all hysterics are malingerers, nor is it correct, nor true. There are some men who won't investigate: who won't admit the influence of the subconscious. The observations of such men are worthless.

The straightforward case of malingering, and the straightforward case of hysteria need no differentiation to the expert. But the statement of Bonnal that a hysteric "is a malingerer who does not lie"; or of Mercier, that a hysteric is "an involuntary malingerer," though being rather witty, are hardly full truths. Everybody will agree that hysteria is a psychic disorder. A hysteric reacts abnormally and persistently to ideas and situations. This is absolute.

I would like to quote a few remarks from Jones and Llewellyn's' interesting and exhaustive work on malingering.

They say all hysterical manifestations are of the nature of unconscious psychical reactions, just as voluntary acts are conscious psychical reactions. Hysteria conforms not to physical but to psychical laws, and more than that, to its own psychical laws—a fact never to be lost sight of by the physician. Its victims to be understood must be measured by the psychologist or psychiatrist.

Nothing resembles malingering more than hysteria; nothing resembles hysteria more than malingering. In both we see the discrepancy between fact and statement, between objective sign and subjective symptom, between appearance of health and the alleged disabilities. Our forefathers regularly mistook hysteria for malingering. Some men in our times take the same view. They show, too, how tests for malingering holding valid in reference to organic diseases, are invalid in reference to hysteria. The variability of symptoms is found in hysteria—*e. g.* anesthesia. To say that they must be fixed, is to gainsay hysteria, and is to make it organic. In other words, neither inconstancy nor variation of symptoms excludes hysteria, nor necessarily proves malingering. There is a profound mental alteration in hysteria.

Hysterics react greatly to mental influences, *i. e.* they are very responsive to suggestion. Thus any direct or indirect suggestion may exert a curative effect, but this does not prove simulation. As Strümpell says, the most diverse conscious and unconscious ideas mingle with one another. Of course, too, it is possible for conscious simulation to be superimposed on hysteria. For would we claim that only normal people can malinger? So we must not call fraudulent any symptoms which appear to us as unfamiliar, variable, or inconsistent. Bouveret and Sanger have mentioned cases of hysterics committing suicide from shame, at being falsely called malingerers. The man who does not grant the difference between organic affections and hysteria will never observe an hysterical person without inferring simulation. This is true of some observers, as we will notice later from some of the opinions, gathered in reference to malingering in the Great War.

The only way to conserve the truth is by unremitting study and observation. As von Frey justly says, the neurological and psychiatric knowledge of not a few doctors is not sufficiently profound to enable them to decide whether the case be one of hysteria or one of malingering. Personally, I feel this applies also to men who confine their studies exclusively to organic neurology, or whose work in psychiatry is purely a narrative or descriptive one. Therefore no physician should diagnose hysteria until he has excluded organic disease; nor diagnose simulation until he has excluded hysteria. We must take a broad view—physical and psychical—to avoid mistakes, and not a narrow or too suspicious view.

The hysteric is deceived by his subconscious; the malingerer deceives others consciously. The characteristic demeanor and behavior of the hysteric, his unconsciousness of the unreality of his symptoms, his extravagance in comparing feelings, etc., compared to the malingerer who is sullen, ill at ease, and who chooses his words carefully—being aware of the unreality of his symptoms—is noticeable. The hysteric is more apt even to slip into inconsistencies than the knave. If you speak of inconsistency to the knave he sulks or tries to laugh, and shows his embarrassment; the hysteric shows a pose and a passionate outburst that is real, in refuting your charge. The hysteric welcomes, the malingerer loathes examinations. The hysteric maintains his characteristics, the malingerer does not, when he thinks he is not being observed. Your psychological study of the personality is of great importance.

Authorities emphasize the fact that the more one sees of neuroses, the less one sees of malingerers. Too many observers assume—not demonstrate—malingering. General experience with careful study and observation of bodily stigmata present, with continuous observations will differentiate simulation from hysteria. To the expert, hysteria offers the greatest difficulty of all nervous conditions, where malingering is suspected. For tests which distinguish organic disease and simulation will not always differentiate hysteria and simulation.

It will be interesting now to review some of the views on malingering as found in soldiers. These opinions are by men who have had considerable experience in the neuroses in the war. We shall notice how they coincide or differ. One or two opinions in regards to malingering and the psychoses are added, and also one as studied in criminals.

Secard[2] says that he has observed a certain amount of malingering in cases of war psychoneuroses. That those with an emotional make-up, with the memory of family responsibilities, are the ones who are subject to psychoneuroses. He says there are no "unconscious malingerers." He speaks of a type who, though at first ill, prefers to exploit and perpetuate his malady, instead of recovering. It goes without saying that if the patient prefers to exploit his malady, and is conscious of so doing, then he is a malingerer. Fear and strained attention, according to Sicard, characterize the true malingerer. He refers to certain subjects of deafness, without organic basis, who remained deaf for months, and classes them as malingerers: 9 out of 17 cases. He quotes the views of some of the more prominent French neurologists on malingering. He says that Pierre Marie spoke of three kinds of malingerers: (1) Those who invent their symptoms—pure malingerers. (2) Hypersuggestible psychopathic or neuropathic individuals, who present motor disturbances, which in no wise resemble organic conditions—unconscious malingerers, he calls these. (To me the conclusions are not scientific nor logical.) (3) Exaggerators, who add motor affections to those caused by actual injury. (One would readily infer that Marie thinks in terms of neurology, rather than analyzing these cases psychologically.)

Dupré speaks of the relation between suggestion and simulation. He says that the following process takes place in a psychopath—shock, emotion, suggestion, exaggeration, malingering, claiming of indemnity. (Unfortunately he fails to show the relation between suggestion and simulation. It is for this reason that the Swiss school is far more satisfactory than the French school of psychopathology.)

Ballet says there are some malingerers who from repetition come to believe their own lies.

Babinski speaks of psychopathic cases of simulation, more or less conscious—which really means that by using the "psychopathic," and the "more or less," that the observer really does not know how to classify these patients; for the characterization of them as stated is ambiguous. In fact it is no clearer than Babinski's definition of hysteria as a disease caused by suggestion and cured by persuasion; which tells you a predisposing cause and his cure, but does not define the disease.

Dejerine says that malingering is less frequent than is supposed.

Gleboff[3] says that recruits, in order to avoid service speak falsely of ailments, which they have not; or use a temporary symptom to avoid duty; they may even mutilate themselves. His Siberian recruits simulated especially defective hearing and vision. Some of them took drugs to affect their heart action. These cases, which he describes, are of course all cases of malingering. However, he tells of some recruits who had undetected disorders, which were not discovered because of the hasty examinations, and yet who were considered malingerers.

Glueck's[4] studies on malingering were conducted on criminals. But we refer to his article here, because it is a very able exposition of the subject. He refers to the well-known fact of malingering and mental disorders coexisting. Malingering is a form of mental reaction to evade a stressful situation, and is resorted to by the abnormal, as psychopaths, hysterics, and the insane. Neither it nor its allied traits, lying and deceit, are always consciously motivated modes of behavior; but they are frequently determined by subconscious motives. (But though there are subconscious motives very likely in lying and deceit, I personally do not feel that we can properly use the terms "lying and deceit," unless the main or one of the main motives is conscious. For a man cannot be accused of lying or deceiving, unless he is conscious of so doing. And certainly the individual can hardly be held responsible for any subconscious motives.) He says it is often extremely difficult to differentiate malingered and genuine symptoms. He, of course, was dealing with a more difficult class of patients than we have had to deal with. He states that pure malingering in normal individuals is rare. Yet in my opinion there is no question but that people who are apparently normal may malinger if the occasion warrants. It is true that such a reaction is abnormal, but still individuals may at times do abnormal things, without being classed among the psychopaths or defectives. Over unconscious motives the individual has little or no control. Malingering is a special form of lying. The law recognizes no intermediary stages between sanity and insanity. At certain times an insane person manifests normal conduct; again, a normal person at times manifests what might be called psychotic reactions. Mental alienation should never be confounded with malingering,

for, as Chavigny[5] says, the sentence of a madman has no value, either as a disciplinary measure or as an example to others.

Lannois and Chavanne[6] refer to some of their patients as being really deaf at the outset from shock, but who later refused to acknowledge the return of hearing. They also mention the careless suggestions of invalidism given by some physicians, which not only are used by malingerers, but which make a deep impression upon the subconscious states of nervous patients. They were of the opinion that the proportion of malingerers was quite large; that in their labyrinthine cases there were more cases of malingering than of incurable deafness. I think that this view is open to doubt, especially when we consider the nature of the cases under observation. The differentiation of simulation and hysteria is outside the realm of the aurist.

Campbell[7] speaks of the great difficulty of differentiating downright malingering, mere exaggerated subconscious malingering (a very faulty expression, I believe), and actual disease. He says that because one merges into the other, this explains the difference in the frequency of malingering claimed by different writers. But the question cannot be cleared up by merely so stating, but rather by noting how they differ, and studying the underlying mechanisms. In my opinion the fault lies with the individual observer—in his satisfaction that his duty is done with a narration or description of the symptoms; and his failure to make an extensive and thorough psychological investigation of the individual case. This writer also refers to the difference of opinion as to the frequency of malingering expressed by the two French neurologists, Déjerine and Marie. He says Déjerine makes the statement that no cases of malingering had come before him, and that the frequency of malingering had been exaggerated, and that recovery after compensation is influenced greatly by the relief of anxiety. Marie, on the other hand, regards malingering among soldiers as being common, saying that 9 out of 40 cases whom he saw were if not malingerers, at any rate exaggerators.

Ballet is quoted as saying that he has met with few malingerers among the French troops.

Wiltshire[8] refers to the anomaly that certain syndromes believed by some to be due to malingering are considered by others to be hysterical. He rightly lays stress on the important influence that the past history of the individual plays in influencing the character of the symptoms as seen in hysteria.

Clarke[9] notes the fact that cases of conscious simulation (and may we ask, what else is malingering?) of nervous disorders have been conspicuous by their absence. He makes a statement, to which all observers will certainly not agree, that only in a limited number of cases does fear of returning to the front retard recovery.

Marriage[10] in discussing cases of deafness says you can usually detect the malingerer by a thorough examination; that such an individual is usually sullen and defiant; as a rule he has his wits about him, and deliberates as to his replies. On the other hand, the patient with psychic deafness has all the signs and symptoms of a patient with a nervous breakdown. Unfortunately Marriage does not emphasize the need of studying the past history, character, and conflicts; but of course, the writer being an aurist, one would hardly expect him to do so. And yet malingering being a psychopathological mechanism, if a man is going to deduce certain conclusions in regard to the subject, he should realize the necessity of understanding the psychobiology of malingering. For is it not true that if a neurologist or a psychiatrist were going to write an article on how to recognize labyrinth disease you would expect him to know what labyrinth disease really was?

To try to detect the malingerer is not a palatable task, Wright[11] says, "but infinite patience and a suspicious mind usually discover the imperfect details of the symptoms or signs." Yes, a suspicious mind can discover almost anything to corroborate its suspicions. But such an attitude is not only highly unscientific in analyzing psychic phenomena, but is hardly a just one with which to approach any patient. How would you compare conclusions reached in this way with those which are founded on a painstaking analytical study, not only of the symptoms and signs but of the patient? He also says that "the shell hysteric or neurasthenic may develop into a malingerer, and the cause is not hidden, nor difficult to find." Such a general statement is utterly valueless if the opinions of the best authorities have any weight. It needs no further discussion. One should realize that a suspicious mind is not the mind that can successfully explore the subconscious; and yet this must be done to get at the real facts. He also says that the "shell neurasthenic" does not recover as quickly as he would if the war were over. Still this does not mean that all such are malingerers, nor does it in any way explain the causes of the neuroses occurring in soldiers, in the hundreds of cases which we have seen in France and the United States since the armistice was signed. No one should be biased in studying these cases. Be suspicious—regard all hysterics as malingerers, at least be so prejudiced—and in regard to your conclusions so deduced you can convince yourself that you are right; but you won't be able to influence, in such belief, even a mediocre student of psychopathology.

Russell[12] makes rather ambiguous remarks in treating the subject. "In all these psychogenetic conditions there is primarily an element of deception." He states that certain types of patients mentally manage to deceive themselves. One cannot help but propound the query "Why mentally deceive themselves?" What importance does consciousness play in his analysis? And what interpretation does he put on the subconscious elements? Is it not so that if deception is present you are dealing with a genuine malingerer? Then he makes the statement that if the patient is allowed to deceive himself too long the more difficult will be the disillusionment. But if the physician knows that the patient is what he calls deceiving himself, in other words is practising deception, why permit it? Why not stop it, and thus cure him? It is self-evident that to deceive and to be deceived are not the same. Such ideas represent much of the vague and indifferent conclusions drawn by some writers on this subject.

It has become fashionable lately to discuss and write on psychological subjects. To use a vernacular expression, much that one reads is mere "bunk." The employment of a few terms used in psychology

does not necessarily constitute a psychological article any more than owning a gun makes one a soldier.

I am referring to these various views just to show the different opinions held on the subject by men in different branches of medicine, and in various countries. It goes without saying, of course, that the opinions expressed by students of psychiatry and psychopathology are the really reliable ones. And with this class of observers there is a real agreement; and we would so expect to find it, for the subject is one which is entirely within their province. Now let us see what the well-known neurologist, Oppenheim,[13] has to say apropos of malingering. He states that many physicians without neurological or psychiatric training are inclined to see malingering in every case that they cannot explain by an obvious organic lesion; that even neurologists who are proficient in organic nervous conditions, but who have had no special psychiatric training, tend to hold similar views. He says, in speaking of Traumatic Neuroses, that some physicians develop an animosity toward these cases, because of the time they consume, and because they have to lose so much time in court because of them. He makes the unusual claim—he is not alone in this conception—that the war has shown that these cases have not only a psychogenic basis, a psychic concussion, but that there is also a peripheral cause, injury of the peripheral nerves. And again Oppenheim[14] maintains his former attitude that a neurosis following a trauma must be considered as a Traumatic Neurosis. At the meeting where he propounded this view he was opposed by nearly all the other specialists present. He said the trauma might be psychic or mechanical; that the idea of a "free interval" does not interfere with the actuality of a physical trauma. His views are too vague, and not explanatory. Nor does he believe that all "war neuroses" are of psychogenic origin; that the war does more than make a fleeting impression on the body" and mind, and that we must be careful in making a diagnosis of hysteria and neurasthenia, or even of simulation. He says also that even an individual who does simulate may also be ill. Though having the most profound admiration for Oppenheim as a neurologist, I cannot say that his exposition of psychopathological phenomena is very lucid, nor are his views on the subject commonly held.

Bönhoffer[15] says that the subconscious influence of desires and wishes can often be demonstrated. He states that the more frequent appearance in times of war than in times of peace of the "pathological fraud—closely related to the hysteric"—is easily understood. Bönhoffer's remarks are true, but one should not get the idea from them that malingering and hysteria are identical, for he is too careful an observer to make any such reflection.

The motivation of psychogenic neuroses, according to Saaler,[16] consists of a subconscious wish to escape the events which produced them whenever there has been an internal conflict. He claims that simulation of neuroses and psychoses cannot be practised by healthy normal men.

Sigg[17] feels that not only simulation, but exaggeration is relatively uncommon. For the great majority of soldiers, the hardships of war were within the limits of human endurance. He states that psychopaths are braced up by mass suggestion, and crowd courage.

Pansera and Chiadini[18] discuss a refractory case of deafness in a man who was given a small amount of ether by inhalation; on coming out he began to talk and showed great joy, which to them was evidence that he was not a malingerer.

Hesnard[19] cautions us not to presume that a patient is a malingerer just because he gives absurd answers to questions, because we know that praecox patients have a habit of doing this. The malingerer cannot simulate the incoherence of the praecox; he is apt to be more absurd than the schizophrenic patient; nor is he spontaneously pleasant or else mocking like the catatonic patient; nor does he play on words and sounds. When a praecox refuses medicine he does so almost instinctively, as possibly from the presence of delusions. The malingerer gives carefully considered reasons for his refusal.

Lyustritski[20] says that nervous symptoms are more difficult to simulate than psychic. A patient cannot simulate the tachycardia and dilated pupils which result in a true neurosis by pressure on a painful area. He claims that they can easily simulate hallucinations and delusions (but are they consistent?), and also affective states. But prolonged insomnia is difficult to simulate; malingerers usually sleep well. He says that verbigeration can be easily simulated. But prolonged typical catatonic states are difficult to feign.

Shumkoff[21] says that military authorities often suspect psychopathic soldiers of malingering. I can confirm this opinion. I know of one officer who made the statement that after nearly every diagnosis of hysteria you should add "malingering." To me a soldier is unfortunate to be examined and treated by such a man. A physician who takes such an attitude reaches such a conclusion because of three factors: his own personality, usually little or no analytical psychological knowledge, his military training. And because of their peculiar narrow-minded interpretation of hysterical phenomena, and their often hasty conclusions, their opinions were usually valueless. If you compare three military writers on this subject with three writers from civil life, of recognized renown, who constituted the real scientific men of the army, the reserve officers, the superiority of the writings of the latter is immediately evident.

Sheehan[22] says that malingering is the effort of an individual to overcome a difficult situation by the production of mental symptoms. (Does he mean conscious effort?) To his remark that malingering often occurs in the subconscious, I must add that to constitute genuine simulation the patient must be aware of it. It is the physician's place to bring the condition into awareness.

At a discussion recently at U. S. A. General Hospital No. 30, where two officers strongly expressed the idea that nearly all hysterics were malingerers, I remarked if they believed that were so, then they should diagnose their cases as malingering, which, by the way, is a crime in the army. But that is where their inconsistency comes in, for I do not know of a single case where they had the temerity to make such a diagnosis. Certainly not on any of the cases from all of my wards. But why not, if you believe it to be true?

I cannot conceive of accusing a patient of committing a fraud—and to malinger is to commit a fraud—and then to reflect that he does not know he is doing so, because the mechanism is subconscious. This is a loose use of language, and also shows a failure to analyze the individual mechanisms. One must be open-minded in judging these cases.

Barker[23] says that while the number of simulators is large, those more experienced in the psychoneuroses believe that the number of true or vulgar simulators is very small.

Neuropsychiatrists in this war have objected strongly to the term "shell-shock" as embracing a multitude of different conditions, stating that one should be more definite in the diagnosis of nervous disorders. For the same reason, in discussing the question as to what constitutes a malingerer I object to confounding malingering, hysteria, psychopath, suggestion, etc.

Chavigny[24] says that patients with true neurotic conditions may resemble malingerers. He cautions military psychiatrists to exhibit an open mind. One must get away from mere customary formulæ, and old principles, for conditions of life are now undergoing a vital transformation.

Again he[25] says that psychiatrists should work in conjunction with court martial boards, as many of the delinquent soldiers show mental disturbances. In his experience malingering is comparatively rare; while one should be on the alert, one does not want to fall into a permanent state of suspicion, and thus commit grave diagnostic errors. For the doctor to mistakenly accuse the patient of malingering is to commit an odious error, and deserves the severest military and medical opprobrium.

Roussy and Boisseau[26] speak of catching the malingerer in the act of deceiving, as being conclusive. But they say that cases of real malingering are exceptional.

Benon[27] is of the opinion that malingering is rather rare in war time, though exaggeration of present motor troubles is common enough. Incipient dementia praecox is often mistaken for malingering, and prolonged and minute observations may be necessary to exclude it.

Bailey[28] in speaking of malingerers said they were more common at National Army camps than among National Guardsmen. But even in the former it never exceeded 1 per cent of the whole command. The motive among these genuine malingerers was to evade service. There is another class of men who really have disabilities, as epilepsy, etc., which they keep from the examiners, in order to get into the service. In other words, they deceive. He says most malingerers are crude, and are easily detected; that few malingerers feign mental or nervous disease. He speaks of illiterates and foreigners feigning mental defect by displaying an unnecessary amount of stupidity. Watch the patient especially when he thinks he is not being observed. The genuine patient rarely complains of anesthesia, for he is usually not aware of it, and if present it synergizes properly with other symptoms and signs. Bailey also says that hysteria is rarely chosen by malingerers for simulation; that the symptoms of hysteria approach those of organic disease closer than can be reproduced by any simulator. In doubtful cases he is sure that an hysterical element is present.

Bispham[29] says a malingerer will give himself away if isolated and carefully observed. He says that the simulation of nervous diseases is much worked over by this class of patients. No doctor, particularly in the Army, is justified in jumping at conclusions; that where a doctor is known to examine all his cases thoroughly malingerers are few and unimportant.

Professor Grasset,[30] who was connected with the French Department of War Neurology, says that fortunately real malingering is infrequent, but there was a class of patients who were ready to exaggerate their symptoms. (Where they consciously do this because of an unethical motive, they are malingerers.)

Régis and Charpentier[31] say that in only one case in sixty-nine did the question of malingering arise; and he was a patient who had been courtmartialed and sentenced.

Strasser[32] makes the statement that the greater the physician's experience the less often he diagnoses simulation.

Kashtshenko,[33] in speaking of insane Russian soldiers, said that only 7 out of 4,069 patients were diagnosed as malingerers, *i.e.* 1/6 of 1 per cent.

Butts[34] says there were only two cases of malingerers in 146 sailors and marines, whom he studied for various psychoses.

There has been considerable discussion in England, according to Welch,[35] who visited the Maudsley Hospital, as to the number of patients who were malingerers. He thought it was impossible that the greater number could be of this type. He mentioned how interesting these cases are to psychologists. On the whole the patients whom he saw showed an inferiority, both psychic and physical.

There may be a merging of the symptoms common to hysteria, neurasthenia, and malingering, according to Lumsden,[36] making the exact diagnosis difficult. (But the picture to be complete must not merely be a narration of symptoms, but an analysis of them.)

Von Sarbo[37] makes the claim that frequent medical examinations and the trying of one therapeutic measure after another are harmful, and may cause a superimposed hysteria. (Here we have a confusing of suggestion and hysteria. The element of fear is to be thought of.)

Mohr[38] states that somatic weakness shown by excessive fatigue, exhaustion, sleeplessness, tremors, and certain motor disturbances, vascular and cardiac affections, paresthesias, etc., may coexist with a psychic predisposition, as shown by an apparent change of personality, psychomotor disturbances, states of anxiety and depression, irritability, phobias, etc. As these often coexist, diagnoses of hysteria and neurasthenia are not often clearly defined. The psychological defense against displeasure exerts a strong influence upon the mental state. The hardships of war lead the individual to seek refuge unconsciously in a neurosis. As Mohr says, you can't cure these cases by "will power." The physician often mistakes these conditions for malingering.

From my own observations on thousands of soldiers, on recruits in the United States, those re-

cently off the battlefields in the A. E. F., and in a special psychoneurotic hospital in America, I would say that in most cases malingering is not difficult to detect, if properly studied.

If the physician erroneously diagnoses a hysteric as a malingerer, he only aggravates the symptoms and delays recovery. These patients should not be sent to special sanatoria for particular symptoms—cardiac, intestinal, etc.—for their associations become psychogenetically fixed on the particular organ, rendering a cure difficult. This is an autosuggestive phenomenon. Never speak to patients about "imaginary" troubles, or the force of suggestion.

Patience, a keen psychological understanding, which all neurologists do not have, and a personal interest in the patient, are necessary to secure results. Under such circumstances you would not hear of so much malingering. Some physicians are apt to suspect simulation, when there has been an inability to effect a cure, especially if, too, there was an absence of physical signs. Much depends, in reaching a conclusion, not only on the physician's knowledge, but on his attitude.

Jones and Llewellyn,[3] in their very interesting book on "Malingering, or the Simulation of Disease," say we find much material for the study of this subject, with the combing of the world for soldiers. They emphasize that this diagnosis must not be made on incomplete examination, imperfect observation, or hasty inference. For my part, I would add that the inference that all hysterics are malingerers, held by some physicians who know little or nothing of the personality and complexes of their patients, but only their symptoms, is pernicious. It is no advance over the ancient lay view that all hysterics are wilfully producing their symptoms, which they could control, if they wished to.

Simulation of insanity is rare according to Hoven.[39] Dementia praecox at the outset often passes for simulation, especially those patients who indulge in silly, absurd, affected behavior. In true simulation the patient is always abnormal—a psychopath. In contrast with actual simulation, exaggeration is common.

Westphal and Hübner[40] say that patients with spasms have frequently been mistaken for malingerers, although various other symptoms or signs, such as convulsions and anesthesia, were present also. The number of real malingerers was not great.

The neurosis is the result of the subconscious, selfish desire to avoid responsibility, MacCurdy[41] says. Weariness and an aversion to fighting are nearly always present. In speaking of malingering he says that error is apt to result, if the physician is influenced by the impression made on him by the personality of the patient, who is usually a psychopath. An exhaustive study may be necessary to determine whether the symptoms are produced on the basis of a conscious or an unconscious wish, which is essentially the difference in etiology, between malingering and hysteria. The patient's attitude, and the history of the onset are of the greatest importance. (Yet in looking over descriptions of cases, we notice frequently the scant attention these factors receive.)

To the genuine hysteric the unconscious motivation, and the fulfilling of the wish by the incapacitating symptom or syndrome are not connected.

I could go on quoting numerous other authorities, but I feel that this is unnecessary to show first what malingering really is; and second, to show why the differences in opinion exist in regards to its frequency.

To conclude that because some neurotics are malingerers, therefore all are, is very poor logic; and it shows poor judgment to say that because the observer is aware of the probable mechanism in a given case the unfortunate patient also knows it. A physician taking this attitude might carry his argument still further, and say that inasmuch as most catatonic precoxes, and also depressive manic patients are, like hysterics, reacting to an unbearable situation, they too are malingerers; even though they are unaware of the connection between their symptoms and the unconscious motivation.

In all cases where a disagreeable situation is unconsciously evaded by an illness, a fundamental factor as to whether a neurosis or psychosis develops, is the underlying personality. The past and present conflicts might represent the artists, the personality, the materials used; and the neurosis or the psychosis, the completed picture. So, needless to say, the same conflicts in different characters and temperaments produce different pictures.

Malingering has been easier to discover in soldiers than in civilians. In medicolegal trials malingering is not at all uncommon, and the motives are on the surface. Criminals are rarely ethical, whereas soldiers are, in the vast majority of cases.

I have had considerable experience in studying the soldiers for the past two years in this war. Nervous and mental boards on which I served in the United States Army camps, examined over 100,000 recruits. Later, in England and in France, for a period of nearly nine months, I observed the soldiers coming from the battlefields, and after the armistice, for four months I had charge of nervous and mental wards in a large general army hospital, taking exclusive care of cases of psychoneuroses.

Also in this time I have been associated with probably one hundred neurologists and psychiatrists —mostly in hospitals or on examining boards— and I think that the opinions of most of these men are the same as those which I express in this paper; and I would say that in all that time and among all that large number of troops, I observed less than a dozen frank malingerers, and practically all of these were marked psychopaths, emotionally unstable, or decidedly inadequate. These cases can best be studied in hospitals, as the examination of recruits was too hurried for proper observation in doubtful cases. The most difficult cases to diagnose were those who had some genuine symptoms. The question would arise as to whether or not there was some exaggeration. Of course, exaggeration of a symptom to avoid an obligation constitutes malingering. I have frequently seen the question brought up in consultations, conferences, and court-martial trials, and before various disability boards on which I served, but it was very rarely that we reached the conclusion that the patient was malingering.

The differences of opinion existing among certain men can usually be explained by the fact that many

writers on the subject have little knowledge of the mechanisms of psychopathological phenomena, and only a moderate amount of experience; some writers promulgate erroneous views, never having reached the real underlying facts. Listening to the narration of a few complaints, finding a more or less negative physical status, and then allowing prejudice to complete the diagnosis, does not help one to reach a happy conclusion. For this procedure will not unearth the past and present ideas, usually subconscious, which are exerting a tremendous pathological influence in the causation of the neurosis.

Also to such observers the subconscious is a mysterious or even an imaginary realm. In other words, it is nonexistant. To deny what one does not understand or know is an easy way to dispose of a doubt, but it is hardly an accurate or scientific method of procedure. Nor is such an attitude compatible with progressive medicine, but rather belongs to the votaries of such chimerical fads as Eddyism or osteopathy.

One must agree, of course, that the hysteric reaction is, as is the praecox way of reacting, a vicious one. But that does not mean that they are all lying and deceiving and feigning illness. While nearly all—if not all—malingerers are psychopaths, it is true, too, that some apparently normal people can malinger, *e.g.*, the society woman who feigns a headache to avoid keeping a disagreeable appointment, or utilizes a mild chronic symptom as her rationalization for not going on a long, unpleasant trip, when her real reasons are more personal.

Would a woman whose husband and children were killed in an automobile accident be a malingerer if she developed a manic depressive insanity as a reaction against her position; or only if she developed an hysteria? In a case like this the conscious elements would seem to be the most overwhelming, but until one had explored her subconsciousness one would not really know just why the psychosis developed. One has to go deeper than rationalizations.

Again, some neurologists are not particularly interested in psychopathological phenomena. Mott of London, and Oppenheim of Berlin, for example, have been prone, during this war, to ascribe an organic basis for certain conditions, where the weight of opinion has been against them.

Again, a thorough schooling in normal and abnormal psychology, wide experience, and a knowledge of human temperament and character, will not suffice for a proper judgment in these cases, if, instead of an open analytical mind, prejudice, which is formed on feeling, is given free rein. For prejudice is not a harbinger for truth. Needless to say, the unskilled and inexperienced writer is apt to indulge in much false speculation on this question.

For a writer to speak of "psychopathic cases of simulation" and hysteria as being identical is not only ambiguous, but erroneous. In this war hysterics, accused of malingering have committed suicide because of false accusations.

I think it is only fair that every writer on this question should first state exactly what he means by malingering, in order to avoid confusion to those who will later scan the literature. After doing this they can then discuss who malinger, the situations which influence malingering, etc. Custom makes language. Malinger means to feign illness. Many writers read into it conditions which do not belong there at all.

A proverbial observation noted in hysterics is the lack of control over their feelings, both agreeable and disagreeable. As a rule with them everything is in the superlative. They describe things as "the loveliest, the most frightful," etc. The question of self-determination and volition in these cases is interesting, but I will not go into them here.

We know that all human beings are creatures of suggestion. Even Dercum,[42] a violent opponent of psychoanalysis, says in his book on "Rest, Suggestion, etc., in Nervous and Mental Diseases," that suggestion is always taking place, usually unconsciously; that a neurotic patient's belief in his recovery favorably affects his condition; that suggestion may act on the mind alone, or may affect a special function of the nervous system. There is no element of malingering here. The physician not only directly employs suggestion, but his own personality offers indirect suggestion.

The dynamic force of fear in the causation of certain pathological mental reactions is well shown by Jones.[43] And are not phobias very common in hysteria? Fear not only produces marked emotional reactions, but physiological, and chemical (metabolic) ones as well. And I mean not only fear of death, but about conditions at home, one's finances, health, etc. Malingering has no place here in the mechanism.

Men whose whole experience is confined to a military atmosphere; men who are engaged chiefly in making accident insurance examinations; or men whose practice is limited to chronic medicolegal expert testimony, no matter how honest they may be personally, are all apt to be unconsciously biased in forming their opinions, and to suspect malingering where it does not exist. So we must frequently accept their opinions *cum grano salis.*

One should not indiscriminately and disconnectedly use the terms hysteria, suggestion, abnormal, psychopath, unconscious, malingering, etc. Put them in their proper setting. Otherwise you will fail to convey a clear idea of what you mean. Were this always done, psychopathology would be more interesting to the average medical man, for the subject itself is a fascinating study. Using terms confusedly is only wearisome to the reader, and an abomination to the student. The statements of some writers are so ambiguous and mystifying that it is questionable sometimes, if these writers really know what ideas they do wish to convey. Mere quasi-psychological language does not make a scientific article.

Do not be content with a mere narration of complaints, but delve beneath the surface for conflicts, motives, etc. It might be well to add here that a person may commit an abnormal act and yet be normal. It is a different matter where abnormal acts are more or less habitual.

In this article I have referred especially to hysteria, as it was by far the predominant neurosis found in the war. However, the same arguments would apply to other neuropsychiatric conditions.

I would like to refer briefly to the following case, which was presented to our disability board at the United States Army General Hospital, No. 30, at Plattsburg Barracks, New York, for disposition:

E. J. S., Pvt. Q. M. C., 25 years old, was drafted against his wishes in May, 1918. He was well until March, 1919. He had never been under fire. He was repeatedly censured rather harshly by his sergeant "for not being snappy enough." He developed a great hatred toward this sergeant, and became very irritable. His history showed him to be a psychopath—emotionally unstable and inadequate. He said he was "'run down," and had a headache, and was sent to the hospital. He was in four different hospitals, two in France and two in the United States, for four and one-half months in all. About the only notes on his brief transfer card were that he was childlike in his reaction, dull, "nervous," and irritable. There were at least three different diagnoses in his case. At one hospital they called him a moron; another diagnosed his case as psychasthenia.

Now, the real facts which were brought out by a few minutes' questioning were, that he merely had a headache lasting but three days when he first went to the hospital in France. After that he had no complaint; yet he spent four and one-half months in the hospitals, being transferred from one to another. His statements evidently were accepted, *i. e.*, that he was "'irritable and nervous"—which might mean much or nothing—and no attempt was made to get at the facts. He frankly admitted to me that his reason for not asking for a discharge at either hospital in the A. E. F. was because he feared he would be sent back to his company and the hated sergeant. It was a plain case of malingering, but our board was against instituting any court martial proceedings in his case, as he was a decided constitutional psycopath. So we recommended his discharge.

This case plainly shows we were dealing not with a hysteric, but with a malingerer. There was no reason why he should have spent four and one-half months in hospitals, as he was as well as he ever had been three days after entering the first hospital. Frequent transfers and a lack of proper observation were the causes of many of these patients continuing in the hospital for too long a period after they were well. Could you picture such a state of affairs happening in a civilian hospital? Three days with a moderate headache, with four and one-half months' rest thrown in!

To speak of unconscious simulation is to say that the patient feigns illness, but that he does not know it. To note that these patients are greatly influenced by suggestion is stating a fact that is hardly a discovery, considering that we are all greatly influenced by suggestion, the chief point of difference being that the normal person, by the exercise of a proper critique, holds the influence of suggestion within bounds.

You will get results in these cases only by getting at the facts. To ignore the real condition, or to treat the patient as a fraud only does harm.

In conclusion, let me reiterate that malingering is the feigning of a symptom or symptoms, or, if really present, the conscious exaggeration of them —all for a definite, selfish, unethical end. It is a fraudulent way of reacting. It is allied to lying and deceit. Suggestion is the psychogenetic influencing of a patient, his condition and his reactions, and may be direct or indirect. The term psychopath designates a constitutional abnormal mental state—a character anomaly. Hysteria is a neurosis, nearly all the victims of which show definite psychopathic traits, even in the interim when apparently well. A hysteric reacts vividly to feelings, ideas, attitudes, and situations; especially when any of these affect any repressed complexes. In hysteria the symptom or syndrome is unconsciously motivated; there is no genuine awareness of the mechanism. The patient is not responsible for the symptoms.

SERUM TREATMENT OF EPIDEMIC POLIOMYELITIS OCCURRING IN DUBUQUE, IOWA, DURING THE SUMMER OF 1918.

By J. J. ROWAN, Jr., M. D.,

DUBUQUE, IOWA.

On June 18, 1918, the first case of epidemic poliomyelitis was reported to the City Recorder's Office as having occurred in the city of Dubuque. It is problematic whether this really was the first instance of the disease here, for there is some reason for suspecting that there may have been a few cases unrecognized, or even possibly concealed from public knowledge. Even after June 18, when cases were reported at regular intervals, there was still no warning of the dangers threatening the children at our very doors. From June 18 to July 5, thirteen cases were reported, and until July 4, when a child of my own developed the malady, it was, apparently, still deemed of insufficient importance to inaugurate any particular measures to suppress the spread of the disease. A peculiar feature of the disease was that it was not confined to any particular part of the city, nor did it tend especially to spread locally where it appeared. A case would be reported from the southern end of the city, and the next case would come from the northern section. It was rather unusual to see more than one case in a family, though this did occur in some instances. It seemed to require more than direct contact to transfer the virus. A soil especially adapted, in the form of defective tonsils or, what to my mind seems more likely, lymphoid tissue in the form of adenoids, seems necessary for invasion to occur. A case in point is the following. A child, living in a good neighborhood and associating daily with twenty other children of the same locality, was the only one to develop the disease. She was also the only one to show evidence of abnormal accumulation of adenoid tissue in her throat. Unhygienic surroundings appeared to play no part in the spread of the disease, for the homes of the well-to-do were, if anything, invaded more frequently than those of the lowly.

Previous to the occurrence of the Dubuque epidemic, I was much interested in the results of the serum treatment by Dr. Rosenow of the Mayo Foundation, of infantile paralysis at Davenport, Iowa, the previous year. The serum used was from horses bled after repeated injections over a long period of time of the pleomorphic streptococcus which he isolates constantly from the central nervous system in poliomyelitis. As is well known, most investigators, notably Dr. Flexner and his coworkers, contend that the etiologic factor concerned in poliomyelitis is a filterable virus, and that it is impossible to obtain a suitable neutralizing serum. I was rather inclined to take Dr. Flexner's word for it, for he had been my teacher of pathology at the University of Pennsylvania, but on the other hand, I could not ignore the contentions of Dr. Rosenow that the streptococcus isolated by him might be the aerobic and antigenic form of Noguchi's and Flexner's globoid bodies, particularly in the light of the results obtained by him in the Davenport epidemic in 1917.

On July 4, 1918, one of my children developed symptoms of poliomyelitis. I immediately communicated with Dr. Rosenow, but by the time he arrived, the child was dead. The object of this paper is not to comment upon this mournful fact, but to present to the profession the impressions of an actual observer of the results obtained by the intravenous injections of this serum in poliomyelitis.

Through the kindness of the Board of Directors of the Finley Hospital, Dr. Rosenow established his laboratory and headquarters there, and personally administered the serum to the majority of these cases, in the meantime teaching and advising the physicians of this community in the early diagnosis of this disease and in the technique of administration of the serum.

The cases presented practically the same quite characteristic general picture. In a few instances the primary symptom was a sudden inability to use a muscle or group of muscles, followed by the usual febrile phenomena, but in the majority of cases the mother first noticed that the child was less active than was its wont. Its inclination was to lie around rather than romp and play. The child was peculiarly restless and wakeful. The symptoms complained of were often so mild that they were ascribed, at least in the beginning of the epidemic, to playing too energetically, to the sun, indigestion, constipation, or what not. The mother described the child as being "off its feed," requiring possibly a dose of castor oil or a few doses of calomel. Close questioning, however, usually elicited a history of a moderately sore throat, but examination usually failed to show marked evidence of inflammation. Palpation of the tonsils, however, almost invariably revealed tenderness, apparently the result of an inflammatory process, deep down in the trabeculæ and interstices of the tonsillar substance, and one or more enlarged lymph glands immediately outside of the tonsils. Pressure on the tonsils often ruptured pus pockets situated

deep down in the substance of the tonsils. An interesting observation in connection with my own cases was that all of them had adenoids or diseased tonsils. It would appear from this that lymphoid structures offer a vulnerable point of attack. This seemed to be remarkably demonstrated in my own family. Of a family of five children, the one that developed poliomyelitis showed unusual resistance to the ordinary diseases of childhood. But she had an adenoid growth that Dr. H. B. Gratiot of this city advised against removal a number of months before the epidemic started here, on account of an epidemic of throat infections which followed throat operations at that time, and which appeared to be confined to persons of this community.

The prodromal symptoms in the cases lasted for a day or two, and then subsided, creating a false sense of security, to be followed in another day or two by a recurrence and marked evidence of involvement of the central nervous system resulting in muscular paralysis. In the initial stages, a very careful examination will elicit, in nearly all cases, weakness in certain muscles or groups of muscles, and this is the time to make a tentative diagnosis. A spinal puncture should be made immediately, and with the fluid under pressure, with a positive cell count and Noguchi globulin test, no time should be lost in injecting the serum. The technique of the administration of the serum is simple. A vein is selected, at the bend of the elbow or at the ankle, or, in the case of a young infant, the jugular is used. The area is sterilized with iodine and alcohol. Where a vein in a limb is selected, compression above is made to fill the vessel, but compression is released as soon as the needle enters the vein. If the needle is properly inserted in the vein, the operation is practically painless. This is not always easy, for occasionally the vessel will persist in rolling away from the point of the needle, and if the injection is not made directly into the lumen, it becomes a painful affair. Injection is made very slowly, fifteen or twenty minutes being required for administering as many cubic centimeters. The dose of the warmed serum is approximately as follows: persons under 2 years of age, 5-15 c.c.; 2 to 5 years, 10-25 c.c.; 5 to 12 years, 15-40 c.c.; over 12 years, 20-75 c.c. If no beneficial action from the serum was noted within eight hours, I always repeated the treatment, except that I gave double the initial dose. In only two or three instances was a second injection required.

The instruments used were an ordinary 50 c.c. Luer's syringe attached to a piece of rubber tubing of small caliber. In the end of the tubing was inserted a small glass tube, carefully ground down by a jeweler until it fitted snugly into a small caliber Luer's needle. For the purpose of obtaining spinal fluid, an ordinary spinal puncture needle was used. The operation is not very painful. Only a small amount of fluid is necessary, and because the spinal fluid is under considerable tension, the pop of the needle can be plainly felt as it goes through the dura. Great care must be exercised not to puncture the anterior wall of the dura and accompanying plexus of vessels because, in the event this is done, admixture of blood is almost sure to occur.

From June 18, 1918, to September 3, 1918, there were 81 cases of infantile paralysis reported to the City Recorder's office. From June 18 until July 5, the date on which Dr. Rosenow arrived in Dubuque, there were 13 cases reported. Four cases which were wrongly diagnosed occurred in addition. One of these died, thus making a total of 17 cases of which 8 died, a mortality rate of 47 per cent. These were all untreated cases. Sixty-eight cases occurred after Dr. Rosenow's arrival. Three patients died during the night immediately prior to the use of the serum. In four of the eleven patients treated with the serum on the first two days the prognosis was most unfavorable. The diagnosis in each of these 68 cases was confirmed by spinal fluid analysis, so that there can be no question as to the correctness of the diagnosis. Dr. Rosenow administered the serum to many of these. The details of the clinical history and other findings will be reported by him. All of the cases which were seen early, before paralysis occurred, and serum administered promptly recovered without developing paralysis. In nearly all of the cases where slight paralysis had occurred, the paralysis was arrested, and all recovered without residual paralysis. In the two that died, the diagnosis was made late. One was a poorly nourished weak baby, two weeks old, who showed no distinct paralysis, but had refused nourishment during a period of seven days and gradually grew weaker and died seemingly of malnutrition. This is included as a case of poliomyelitis almost wholly on the spinal fluid findings. There were a positive globulin test and 40 cells per cubic centimeter. One subcutaneous injection of 6 c.c. of serum was given with no apparent effect. The other death was in the case of a girl of 18 years, who had been severely ill for four days. A rapidly progressing paralysis of the ascending type began thirty-six hours previously. At the time of the first injection there was practically complete paralysis of both lower extremities, paralysis of the muscles of the back, of the bladder and rectum, of the left arm, a marked weakness of the muscles of the right arm, neck, and muscles of deglutition, and marked shortness of breath with cyanosis owing to involvement of the muscles of respiration. The temperature was lowered and the paralysis was arrested for forty-eight hours. Eighteen hours after the third injection of serum, respiratory embarrassment recurred and the patient died twelve hours later.

In the remaining patients with advanced paralysis, the progress of the disease was arrested in those in which it was progressing. A distinct improvement in muscle function occurred soon after injection in those in whom the paralysis had become stationary. Post-paralytic pains, if still present, were relieved, as long as ten days after onset in those in whom the spinal fluid still showed evidence of activity of the process. In only three cases treated with the serum is there residual paralysis, and in all of these the serum was administered late, in one case on the third day, in the other two, on the eighth day after paralysis had set in. I have seen improvement manifest in 15 minutes' time, and in 90 per cent. of the early cases convalescence was well established within 24 hours. Indeed, in a number of my own cases, no evidence existed on the following day that the child had ever been ill. These apparently striking

effects of the serum have been witnessed by members of the profession in Dubuque, and the statement is in no sense an exaggeration of the facts. In a very few instances, and notably in a severe case which I saw in consultation with Dr. Snyder of Freeport, Illinois, the serum, while it aparently saved the life of the child, seemed incapable of halting completely the effects of the virus, and there occurred a considerable degree of disability. This was the only case in my own practice in which the serum seemed not to act promptly.

I noticed a symptom in the case of my own child, the import of which I did not realize at the time, but which stood me well in hand in subsequent cases, and which is well exemplified in the following one. On July 29, Mrs. F. called me on the phone, and told me that her six-year-old girl had complained that morning of a headache, but was now apparently all right, playing around as usual, but because of the presence of the epidemic, she thought that she had better speak to me about it. I saw her about 11 A.M., when the mother said she had been unduly alarmed, for the girl now appeared well. On picking the child up under the arms, however, I immediately noticed a sensation as though the child was rotating on her spine. I had noticed this before in a case that developed marked paralysis, and on the strength of that alone, I made a spinal puncture, and found the fluid under pressure, a cell count of 15, and a positive globulin test. It was necessary to return to my ice-chest for the serum, and when I returned to the patient about one hour hater, I found the child paralyzed in both legs and one arm. The child had developed a rise of temperature during my absence, and her head was markedly retracted. A professional friend, who had seen the case with me an hour before, had scouted the idea of the existence here of poliomyelitis. Twenty-five c.c. of serum were injected, and the following morning no evidence existed that the child had ever been ill. This child was a mouth-breather from adenoids, the only one of three children who had abnormal lymphoid tissue in the throat, and the only one that contracted the disease.

With the administration of the serum in this epidemic, I know of no instance of any severe serum sickness. In three of my own cases, an urticaria developed; in two, of quite a severe type, but it rapidly subsided. In a number of instances, I had previously administered diphtheria antitoxin, and in these cases I injected one-half c.c. of serum and waited an hour, when the entire amount was given.

It appears to me that the lessons taught by the epidemic in Dubuque may be summarized as follows: In the presence of epidemic poliomyelitis anywhere in the country, all instances of obscure disturbances in children, especially under 10 years of age, and particularly if associated with any digestive disturbance or intestinal irritation, should be subjected to the closest scrutiny until the diagnosis is made plain. In the event of a case developing poliomyelitis, the fact should be made known in order that parents may be on their guard, and not ignore any disturbance that may develop, however mild, and especially if associated with an intestinal irritation. It would appear that a greater effort should be made to impress upon parents the importance of having all cases of adenoids promptly attended to by a competent specialist, and I believe the word "specialist" should be emphasized. If a second case should develop, all places of congregation for children should be closed. Just how effective this procedure is, I do not know, for the disease appears to attack certain children, no matter how closely they may be guarded, but I think, as a precautionary measure, it should be carried out. During an epidemic, every child showing the slightest indisposition should be examined with the most minute care for any suspicious muscle weakness, and in the abscence of any definite evidence of other disease, a spinal fluid analysis should be insisted upon. With the fluid under pressure, and if the conditions are such that the specimen must be sent to a distance for analysis, no time should be lost in waiting for the pathologist's report, but the injection made at once. If the disease is not present, no harm is done, and delay may mean the difference between a healthy child and a hopelessly paralyzed one.

The serum appeared to be as certain in its action as is antitoxin in the treatment of diphtheria. A feature of these recoveries which is as pleasing as it is important to the medical profession at large is the fact that in about 95 per cent. of the cases there was left nothing to indicate that they had ever had the disease. Of the 85 cases of epidemic poliomyelitis which occurred in Dubuque, 10 died, a mortality of 12 per cent. Seventeen were not treated with the serum; of these eight died, a mortality of 47 per cent. Sixty-eight were treated with the serum, and of these two died, a mortality of 3 per cent. In the two cases that died, conditions were such that curative effects of the serum could not be expected. The ages of the cases ranged from two weeks to eighteen years. The average age of the untreated group was 4.8 years, and the average age of those treated was 4.7 years. The great majority in each group were under six years of age. The disease was about evenly distributed between boys and girls. There was no lull in the epidemic between the treated and untreated groups. The crest of the wave of the epidemic occurred seven days after the serum treatment was begun. There was no difference in the severity of the early symptoms in the two groups of cases. The differences in mortality and incapacity would seem, therefore, to be attributable to the good effects of the serum.

I am indebted to the members of the Dubuque County Medical Society, without whose cooperation in supplying the necessary information in regard to their cases, the preparation of this report would have been impossible.

1022 Bluff Street.

Jennerian Vaccination and Whooping Cough.—Jenner himself taught that freshly vaccinated children do not contract whooping cough and since his day physicians have frequently tried out this prophylaxis with varying success. Calf serum has been tested in the socalled Violi method, the vaccine being prepared especially for pertussis by freshly vaccinating the animals. The results from all methods are so conflicting that only a limited protection can be counted on. Lederer saw nine apparent protections in 18 exposures when revaccination had been practised after failure of primary vaccinations. — *Correspondenz-Blatt für Schweizer Aerzte.*

THE RESULTS OF FOCAL INFECTIONS AS SEEN IN OPHTHALMOLOGY AND OTOLARYNGOLOGY.*

By B. D. RAYDIN, B.S., M.D.,

EVANSVILLE, IND.

Focal infections and their results on neighboring and remote organs is an interesting and very important subject. Those of you who are familiar with the work and investigation of Billings, Rosenow, Duke, Haskins, Brown, Irons, and many others, will agree with me that the subject deserves our serious consideration and discussion. In this short paper I will call your attention for a few minutes to the results or effects of infectious foci as seen in eye and ear practice.

By the term focal infection as used in this paper I am referring to a circumscribed or localized infected area or lesion from which infectious materials or toxins are carried to distant organs.

The foci of infection with which the oculist and aurist becomes more intimately familiar are principally the triad of the so-called oral sepsis, dental caries, alveolar abscess, and pyorrhea alveolaris; tonsil infections, suppurative sinusitis, chronic otitis media, and intestinal toxemia. This paper deals only with facts not with theories.

Just as endocarditis, periostitis, neuritis, arthritis, osteitis, appendicitis, and a host of other -itises and -emias have their origin in a number of cases in oral sepsis, tonsillar and other foci of infection, so too we see conjunctivitis, episcleritis, scleritis, keratitis, and various forms of endogenous uveitis resulting from focal infection.

Chronic conjunctivitis of a low grade, seen daily by everyone of us, is in a great many cases closely allied with or dependent on focal infections. I have seen many cases where there was an associated disturbance of the alimentary tract and just so long as this disturbance was present the patient continued to complain of his eye trouble. A quiescence of the alimentary disturbance promptly caused the patient's eyelids to feel very much better. Again I have seen chronic conjunctivitis persist in spite of all form of local treatment until diseased teeth and tonsils have been removed.

Episcleritis and scleritis are very frequently associated with dental infection, and many of these cases will not improve until all evidence of oral sepsis have been thoroughly eradicated.

The cornea is very prone to endogenous infection and is with the iris, ciliary body, and choroid probably more often affected than the other membranes of the eye. Eliminating interstitial keratitis, which is due in the majority of cases to syphilis or tuberculosis, we have a large variety of corneal affections probably of focal origin.

I have now under observation an interesting case of a lady in middle life with keratitis profunda. Practically the entire cornea shows an extensive grayish infiltrate in the deeper layers. She had been under the care of an out-of-town physician for a month with apparently no marked improvement. Upon my first examination of the patient I suggested the possibility of a focal infection as the causative factor. Her tonsils had been previously removed. Her teeth apparently looked excellent, she never had an ache or pain from a tooth; however, a Roentgenogram of her teeth disclosed an apical abscess of an upper molar on the same side as the affected eye. The tooth was removed and the corneal infiltrate is now rapidly clearing up.

Iritis is now looked upon as having a varied etiology. The majority of cases are due to lues and gonorrhea, nevertheless we frequently find iritis brought on by a focal infection. This class of cases in years gone by were looked upon as rheumatic or idiopathic. I have just discharged a patient whose iritis was of tonsillar origin. One week after the onset of a severe tonsillitis an iritis developed. This was the second attack of iritis following acute tonsillitis. The tonsils in this case were removed and the iritis promptly subsided.

During the past year my father and I have had an opportunity to study in our practice a series of cases of uveitis, all in women and peculiarly all in the left eye. In all these cases one or more foci of infection were found. Every source of infection was removed and all made excellent recoveries save one whose uveitis was of the malignant type. This patient developed a cataract in the affected eye in spite of everything that was done. In this particular case blood and spinal fluid Wassermann were negative; the tuberculin test was negative. The tonsils were removed, the infected ethmoid cells were exenterated, everything was done, and yet the eye showed no improvement. I feel in this particular case that the focus of infection responsible for the trouble has not been found.

Among the series of uveitis cases was a young lady referred from Washington, Ind. The examination showed beyond any doubt that we had a case of uveitis. Everything was done for this patient that had been done in the other similar cases, but her eye showed no marked improvement. About two months after our first observation of the case she developed an acute exacerbation of a chronic appendicitis. Her local physician removed her appendix and within one week the eye showed an improvement in vision and she promptly made an excellent recovery. This case serves well to illustrate that we must often go beyond diseased teeth, tonsils, and sinuses to find our focus of infection.

What has been said of the preceding eye disorders, and a great deal more remains to be said, holds equally true for certain cases of choroiditis, retinitis, and optic neuritis. Here too, we find, aside from syphilis, tuberculosis, and chronic nephritis, which must never be forgotten as possible causes, the possibilities of focal infections entering into the etiology of these diseases.

In the domain of otology the relationship of chronic foci of infection, while not so extensive, nevertheless is present in a sufficient number of conditions to warrant our constant attention for this source of infection.

We are well aware of the fact that a chronic suppurating ear is in many instances kept in this chronic state by infected tonsils and adenoids or infected accessory sinuses. Only by the thorough eradication of these foci of infection can we in any measure hope to control the discharge from that

*Read at the twentieth annual session of the Ohio Valley Medical Association at Evansville, Ind., November 11 and 12, 1919.

ear. Then again a chronic suppurating ear may be the cause of a metastatic purulent panophthalmitis, necessitating the enucleation of the eye.

In the newer work on neuro-otology we often find an irritative or toxic labyrinthitis due to chronic foci of infection elsewhere. A case under my care about one year ago will illustrate this point.

Mrs. S. presented herself with the history of marked vertigo, staggering and tinnitus, at times so severe that she was compelled to go to bed, and even then the dizziness persisted if she lay in certain positions. She had previous to her coming to our office been treated for stomach and liver trouble. A complete eye and ear examination was made, including the turning test with the Bárany chair, and the findings brought me to the conclusion that I was dealing with an irritative or toxic labyrinthitis due probably to an infective focus somewhere in the body. There was no intranasal or sinus pathology, the tonsils were healthy. A Roentgenogram of her teeth was made and the film showed an extensive destruction of the lower central incisor with a very large apical abscess. This tooth and the two adjacent teeth on each side were removed, the alveolar process was curetted, and the patient made an excellent recovery. Her vertigo disappeared and she was not disturbed by dizziness, staggering, or tinnitus.

I have another patient with an identical history. The findings were very similar, dental infection was found, the diseased teeth were removed, and all vertigo disappeared.

I might go on for some time citing cases and results, but the above is sufficient to illustrate what I wish to call your attention to. I cannot too strongly emphasize the necessity of deliberate and constant search for all foci of infection, especially in patients that present endogenous eye conditions. The dangers of septic foci being overlooked in a hasty examination cannot be too strongly emphasized, for the toxemias resulting from them are most insidious and far-reaching, no part of the body being apparently exempt from attack.

The activities of professional research within recent years in the domain of focal infections have been well-nigh colossal and he who moves not with the front ranks is in danger of lagging in the rear. The effect upon a young practitioner of a cabinet or surgical instruments often creates a vision of the surgical achievements of the Mayos, Cushing, Lane, et al., unmindful of the fact that the labors of Osler, Billings, Rosenow, and others have been equally brilliant in their results in the field of medicine. The successful physician of today must possess a mental horizon which will enable him to be receptive to new truths and a willingness to work patiently to contribute to the world's store of knowledge.

Citizens National Bank Bldg.

Arbuthnot Lane's Disease.—Thus Pouchet designates chronic intestinal stasis. He suspects the presence of chronic intestinal stasis in so many conditions that he would radioscope every patient with gastric, intestinal, or abdominal symptoms, or with anemia, neurasthenia, and circulatory troubles which do not respond to treatment based on the supposed cause. One radioscopy is far from sufficient, so he would make at least 3 or 4, spaced at from 12 to 24 hours. Chronic intestinal stasis may, of course, complicate many other affections, as nephritis, tuberculosis, and cancer, and add to the disease picture. Mild, or medical, and surgical cases are regarded as two successive stages of one disease.—*Journal de médecine et de chirurgie pratiques.*

Medicolegal Notes.

Permits for Hospitals in New York City.—Under sections 1167, 1172, of the charter of the city of New York, the board of health has general jurisdiction over the establishment and maintenance of hospitals, including their licensing. The New York Court of Appeals holds that the board had no power to refuse a permit for a private hospital for the treatment of medical, surgical, and obstetrical cases, as required by its Sanitary Code, section 220, when all other conditions were satisfactory, and no offense to the senses was suggested, for the exclusive reason that considerable damage would accrue to surrounding property.—People v. Department of Health (N. Y.), 123 N. E. 379.

Medical Evidence as to Cause of Injury.—In an action for personal injuries claimed to be the result of a collision it was proved that the plaintiff had, prior to the accident, and still had, a displaced kidney, and that neurasthenia could be caused by such displacement. When, however, the medical experts of the defendant were asked at the conclusion of hypothetical questions stating the substance of the testimony, "Can you say with reasonable certainty whether or not the misplaced kidney is a competent producing cause of her neurasthenic condition?" the question, on the objection of the plaintiff's attorney, was excluded by the court. On appeal this was held to be error as the question had an important bearing on a vital issue of the case, whether the plaintiff's injuries were the result of the defendant's negligence.—Komoll v. Shults Bread Co., 175 N. Y. Supp. 775.

Submission to Operation.—A workman claiming under the Michigan Workmen's Compensation Act who had received, in the course of his employment, an accidental injury resulting in a hernia, was tendered an operation, which both his own and the company's physicians advised. The evidence showed that the operation could be performed without administering a general anesthetic, by application of a local anesthetic, that it would not endanger life, and that the plaintiff could not be cured of the hernia without it. The claimant refused to submit to the operation. It was held that his refusal to follow the advice and judgment of both physicians relieved his employers from further activities in that direction, and for the time being, at least, absolved them from liability. The court quoted with approval Donnelly v. Baird, 1 B. W. C. C. 95, as follows: "That if the operation is not attended with danger to life or health, or extraordinary suffering, and if according to the best medical or surgical opinion the operation offers a reasonable prospect of restoration or relief from the incapacity from which the workman is suffering, then he must either submit to the operation or release his employers from the obligation to maintain him."—O'Brien v. Albrecht, Michigan Supreme Court, 172 N. W. 601.

Medical Evidence as to Cause of Death.—In an action to recover for death under an accident insurance policy it appeared that the assured, a motorist, was found lying dead beside his automobile, which was of an old-fashioned type, cranking on the side. When the body was discovered the machine was all ready for starting except the cranking; the crank was lying on the ground a few feet away. The car was difficult to crank, and on several occasions it had back-fired, causing the crank either to fly off the machine or strike and injure the person who was cranking it. The autopsy showed the deceased to be free from any sort of disease; the vital organs were normal. There was a small mark, about an inch long and half an inch wide, on the breast, immediately over the heart, which was described as a sort of fresh bruise, made by a blunt instrument like the crank, striking him a blow at that point. Medical experts testified that a blow at that point from a blunt instrument, with force sufficient to produce such a bruise, might cause death by paralyzing the action of the heart, and they gave it as their opinion that the death was from paralysis of the heart caused by a blow received at the point where the bruise was located. The Illinois Appellate Court held that the evidence was of such character as to require the submission to the jury of the question whether the death was by external, violent, and accidental means.—Lamoreux v. Illinois Commercial Men's Assn., 212 Ill. App. 263.

New York, December 13, 1919.

THE QUALITY OF OUR MEDICAL STUDENTS.

IF one were to obey the impulse to criticise the personal qualifications of our physicians and surgeons, nothing could be more natural (or more easy) than to say, "Begin with the medical schools. Weed out the undesirables before they become doctors." Or, better still, begin before they become medical students. Certainly if any weeding is to be done charity demands that both victims and teachers be spared as much as possible. Although we have not yet recovered from the bad effects of the inferior medical schools, these have for the most part been obliged to go out of business because of the rising standards of medical education. Premedical training may now be said to be adequate, in the sense that students enter the medical schools equipped to assimilate what is taught them in the first year, without wasting time on subjects that should have been learned in college. The difficulty of acquiring an M. D. and a license having been thus increased, the student's zeal must be correspondingly great in order to tide him over such a period of training.

We should accordingly expect to find the medical schools attended by more eager, high-minded youth than could be found in any other institution of learning. But one of the most unpleasant facts that the finer type of medical student has to confront is that some of his fellow students are profane, ungentlemanly, obscene to a surprising degree. How any school can make of these men the refined, sympathetic practitioners whose presence would inspire patients is beyond all imagination. Fortunately men with low ideals are undoubtedly much less common than those with high ideals. In the medical schools as everywhere there is a larger middle group of "the moderately desirable."

Naturally we want to exclude as many undesirables from the profession as we possibly can. But what is an undesirable? Certainly not necessarily that rough, boorish personality, socially lowbrow, who often answers the call of science. If we boycott this type we run the risk of aligning ourselves against potential Parés or Hunters. One need not have a dancing master's manners in order to be a valuable medical man. A Committee on Admission should first, of course, ascertain the adequacy of the candidate's premedical training. It should then take the trouble to look much more carefully than is now the rule into the candidate's general record in high school and college. Men with a history of flagrant immorality will bear careful watching before they can be considered fit material for hospital staffs or for any professional work. It should be borne in mind that abortionists and dope distributors, as well as many of the advertising quacks, are recruited from our medical schools.

More important still is the necessity for a thorough physical and mental examination of the candidate himself before he is granted admission to the school. It is astonishing how few schools require this. Perhaps as the list of students who develop tuberculosis or the various psychoses continues to increase, more medical schools will realize the necessity of overhauling the physical and mental equipment of those who face such strenuous years of study and activity. Only a few, however, will be excluded as a result of the disqualifications mentioned.

The one which should affect more students, eliminate more deadwood from the schools, and be of most ultimate benefit to the profession, is that of dilettantism. There are too many dabblers in medicine. There are too many who never had a good and sufficient reason for entering the profession, who have little or no desire to contribute to its progress except in so far as so doing will help themselves. Such students may scrape their way to the M. D. degree; may achieve the State license. But in the hospitals they are the bane of the attendings. Their interest in the service is slight compared with their interest in time off. They are deadwood indeed. How discover these in time? And how at the same time do justice to the man who does not "warm up," who does not do justice to himself till he gets well started in his medical studies?

Fortunately the answer is simple; and a few of our better medical schools are already making it. Make the requirements harder. Make the training longer and still more thorough. Requiring four instead of two years of college work will do away with that narrowing of the student's horizon, that blinding of his vision to other fields of endeavor, which is secondary to two years crammed with courses in science. It will give the student a maturer mind and more time to make his choice of a life-work. And then, lengthening the medical curriculum to five years, the professional advantages of which are too obvious to recount, will require added conviction on the part of the student that his choice of a profession has been the right one. He will be that much less likely to "drift" into medicine.

Making the road longer and harder to travel, requiring more maturity of the wayfaring student, together with a more rigid appraisal of his equipment for the journey, cannot but result in leaving more of the unfit by the wayside, and improving very greatly the quality of those finally authorized to treat the sick.

CHONDROMATA.

Chondromata, composed originally of typical hyaline cartilage, may undergo various transformations, such as fatty or glycogenic infiltration, which are benign, but an osteoid chondroma with marked calcareous infiltration, may present the evolution of a malignant neoplasm, and when the growth undergoes a sarcomatous transformation its malignancy is very marked. Chondromata belong to young subjects and may develop after a traumatism, while instances of an apparent hereditary taint have been recorded. A very intimate relationship exists between chondromata and osteogenetic exostoses. Both these morbid processes appear to be derived from small cartilaginous masses which become isolated during the early phases of development of the bones. They often accompany disturbances of growth. In the extremities, chondromata take on a spheroidal shape, their surface is bosselated, and in consistency they are firm and elastic. Usually they interfere little with the movements of the joints except when they have attained considerable size or have multiplied. In other bones, particularly those of the thigh and pelvis, they reach large dimensions, palpation gives various signs, and the skin over the tumor ulcerates with greater ease than elsewhere. The patient's general condition will usually be satisfactory. A chondroma usually grows slowly but impressively. These neoplasms are generally benign and metastases have been but rarely observed. Nonmalignancy is all the more evident when the chondroma is seated in the bones of the limbs. It must be remarked, however, that chondromata following upon the exostoses of growth often present a certain degree of malignancy.

The diagnosis is at times a matter of some difficulty, especially when the chondroma is seated at the root of a limb. The limitation of the growth, the slowness of its evolution, and radiography will distinguish it from sarcoma and other neoplasms springing from the bones.

Chondromata should be removed as soon as possible. When the growth is yet small and superficially seated, when the bony shell has not been entirely destroyed, or if the tumor, although large, is situated on an epiphysis, exsection may be essayed. But in all other circumstances amputation, as a rule, seems to be the only justifiable procedure.

The Syphilitic Etiology of Epilepsy and Idiocy.

Epilepsy in all its forms may be caused by syphilis. Acquired syphilis gives rise to a secondary form of epilepsy, probably due to toxic changes arising in the nervous system, while a gummatous tertiary form has also been described. Hereditary syphilis is the cause of about 33 per cent. of all cases of idiocy and epilepsy, according to Bertin and Gayet, and these two affections may coexist in the same subject. It is, however, a fact that in a very large number of cases it is quite impossible to establish definitely the syphilitic origin of epilepsy or idiocy by means of ordinary clinical exploration; but there seems to be no doubt that the Wassermann reaction will assume an important place in the diagnosis of syphilis in epileptics and idiots. In practically all of these subjects the clinical data are obscure and search for the spirochete remains fruitless so that the Wassermann test should be resorted to. It is evident, however, that this diagnostic means cannot offer the same rigorous certitude that would be given by a clean-cut clinical picture or the finding of the spirochete in the lesions, but regardless of these imperfections it gives in many cases data of really great importance clinically, and for this reason it should be essayed in all cases where the etiological diagnosis is uncertain. It would seem that there is good reason to submit epileptics or idiots to specific treatment when a Wassermann indicates that the possibility of syphilis exists; this treatment could be essayed in the absence of any former or present specific manifestation. It will be all the more likely to be successful the earlier it is given and the greater its intensity. The Wassermann reaction is far from possessing an absolute value; nevertheless it appears to have a relative value and may render considerable service. It certainly should be tried because it constitutes yet another presumption in favor of either acquired or hereditary syphilis, and in certain cases—unfortunately too rare—it has been the means of confirming the diagnosis. It should be repeated because when constantly positive it is a sign of great probability, if not of absolute certainty.

Virus of Typhus Fever.

Sampietro, discussing European typhus in the *Annali d'Igiene* for August 31, 1919, xxix, 8, reviews no less than eight alleged causes. These are in succession the *Diplobacillus exanthematicus* of Rabinovitch, cellular inclusions, the Rickettsia, the Plotz bacillus, the Weil-Felix bacillus, filtrable virus, no specific virus (the disease being regarded as a mere syndrome), and finally the view that the disease as we know it is the product of secondary infection. The author does not commit himself in favor of any one of these alleged causes. Neither does he absolutely rule out any of them as causes—if the syndrome theory should chance to be the correct one, who could say that several of the organisms were not equally responsible for the totality of the disease? Rabinovitch and some of his followers are still convinced of the pathogenicity of their bacillus, while Proescher and others are still believers in the cell inclusion hypothesis. The Rickettsia receives much space, but the author is not one of those who regard it as the proven cause of the disease. Its study has brought home to us the fact that the louse transmits the virus, but the complete chain of proof is not yet forged in favor of the Rickettsia. The author seems rather prepossessed in favor of Plotz's bacillus, for it has been found in various countries in association with the disease, and in animal experiment has given some decisive results. Naturally by reason of the Weil-Felix reaction the germ accused by them receives much notice. Negative blood cultures have, however, proved a stumbling block for the proteus. The theory of a filtrable virus is the least satisfactory of all, in the au-

thor's opinion, although some positive experiments have been reported. No evidence is adduced in support of the syndrome theory, but the analogy of typhoid makes such a view tenable. The belief that the disease typhus is due to secondary infection does not exclude the possibility of one of the preceding theories and would harmonize, for example, with that of a filtrable virus.

Swiss Birth Statistics.

A survey of the marriages, births, and deaths in Switzerland from 1881 to 1918 shows that the marriage rate per 1,000 remains nearly constant, while the birth rate has declined strikingly, especially since 1910. The deaths have been falling off somewhat, but by no means enough to offset the low birth rate. The country has never had the high birth rate seen in some of its neighbors, and among 21 European lands is fifth from the last (which is France). The influence of the great war in the decline of the birth rate is apparent, although Switzerland did not participate. In Basle the birth rate in 1914 was 18.37 and in 1917 it was 12.7. Other cities show similar figures. An enormous increase in the death rate of 1918 was due, of course, to the influenza pandemic. The fertility of the agricultural classes greatly exceeds that of the factory workers, for the former are better able to nourish their offspring. But the prosperous and well to do, who are also favored in this manner, are much less fertile than the proletariat. Again, the undesirables, such as alcoholics, multiply while the intellectuals abstain. These tendencies oppose each other and aside from the rural element already mentioned, the better ranks do not reproduce themselves. Hence not only does quantity fall off, but quality as well.

News of the Week.

State Insurance Fraud.—According to the report to Governor Smith by Jeremiah F. Connor, appointed last February to investigate the management and affairs of the State Industrial Commission and the State Insurance Fund, injured workingmen and women of New York State have been defrauded of at least $5,000,000 through underpayments and the failure to detect an organized system of grafting. Mr. Connor makes twenty-seven recommendations for the correction of the abuses which have developed in connection with the determination of awards to beneficiaries under the Workmen's Compensation Law and with the management of the State Fund. Fifteen of these recommendations advocate changes in the existing legislation; the other twelve deal with the reorganization of the Fund.

Faulty X-Ray Machine Electrocutes Physician.—Dr. Jangeas, in charge of the *x*-ray work at the American Hospital at Neuilly, was electrocuted while preparing to treat a patient. The Coolidge apparatus used for transmitting the rays suddenly burst into a terrible fusilade of sparks, the shock of which produced instant death.

Dr. Charles Karsner Mills has resigned as Visiting Neurologist to the Philadelphia General Hospital, a position he has occupied for more than 30 years, and he has been elected Emeritus Neurologist. He is succeeded by Dr. J. D. McConnell.

Miss Eva Parmlee, of Springfield, Mass., was given the decoration of the Royal Red Cross by the Prince of Wales during his recent visit to this country. Miss Parmlee, who was a member of the Harvard Unit, served in the United States Base Hospital No. 5, on the British front. On September 4, 1917, at Dannes Caniers, she was struck by splinters during a German air raid.

Medical School Established in the Caucasus.—The gift of supplies and equipment for the new City Hospital at Ekaterinodar, in southern Russia, by the American Red Cross, has resulted in the establishment of a first-class medical school in the Caucasus. The hospital, which occupies the former high school building or "gymnasium," is complete with wards containing 350 beds, laboratories, and three operating rooms, and is one of the most modern buildings in the country. Medicines, instruments and supplies for equipping the hospital were landed from a Red Cross ship at Novorossick and were installed under the direction of Dr. J. J. Szymanski, of Passaic, N. J. The staff includes some of the best professors and surgeons of Petrograd and Moscow, who fled to the Cossack state at the beginning of the Bolshevist régime. Professor Alexiensky, formerly of the University of Moscow, is chief surgeon.

Keeley Institute Closed.—The Keeley Institute at White Plains was recently sold at auction under a foreclosure judgment. It was bought by two New York physicians who propose transforming it into a sanatorium for the treatment of nervous affections.

Industrial Training for Cripples.—The Institute for Crippled and Disabled Men is to continue its work under a new Board of Trustees. The American Red Cross, according to its announcement, having withdrawn as directing authority of the Institute. The Red Cross has made a grant of $5,000 to be expended by the new board.

Town Without a Physician.—According to press reports the town of Charlton, Mass., is without a physician, in consequence of the death, some time ago, of Dr. Paul W. Abell. For a quarter of a century Dr. Abell was the only physician in this town of more than 2,000 population.

Food Distributed Upon Physicians' Prescriptions.—According to unofficial advices received by the State Department from Helsingsfors, November 25, the food shortage in Petrograd had reached such an acute stage that food was being distributed only upon prescriptions of physicians.

Turtle Serum "Socialized"? — Press reports from Berlin announce that Dr. Friedrich Franz Friedmann has sold the rights to his turtle serum for tuberculosis to two prominent Social Democratic capitalists for 700,000 marks.

Army Base Hospitals Organized by American Red Cross to be Held Intact.—In accordance with the wishes of the military authorities, and as part of the peace program of the American Red Cross, base hospitals organized by the Red Cross for the Army will be held intact against future emergencies—floods, earthquakes, epidemics, and, of course, should it ever come again, war. There are fifty of the hospitals located at important points

throughout the country. Their personnel is recruited from the staffs of the hospitals in their vicinity. The Army is co-operating with the Red Cross by providing each base hospital with a unit of equipment in accordance with military standards, stored in a Government storehouse as near as possible to the city in which the base hospital is situated. Red Cross Chapters, also, are assisting in the reorganization of these hospitals for peace times.

Chlorinated Highballs for Polish Soldiers.—Last summer the Polish army called upon the American Red Cross for assistance in improving health conditions in its camps and military centers. As a first step in starting health improvements the Red Cross pointed out the advantages of the Lyster bag—"the doughboy's life-saver"—for the purification of drinking water, a sanitary measure not previously employed in the Polish army. Following the suggestion of the Red Cross, Polish chemists made tests of the action of the Lyster bag, and endorsed it highly. As a result the Minister of Health ordered 20,000 of these bags, together with the necessary ampoules of calcium hypochlorite, for use in army camps and at civilian refugee centers. And now the "chlorinated highball," long familiar with the A. E. F., promises to be the popular beverage in Poland. Slow evaporation through the canvas, when the bag is hung out of doors, keeps the water cool, and the tube of calcium hypochlorite broken into it makes it safe for drinking.

Mobile Field Hospitals for Siberian Armies.—The American Red Cross has supplied the Siberian Armies with two mobile field hospitals in box car units.

Society of Medical Jurisprudence Elects.—This organization at its regular meeting held December 9, 1919, elected the following officers for the ensuing year: President, Dr. Nathan B. Van Etten; Vice-President, Charles Oakes, Esq.; Treasurer, Charles P. Blaney, Esq.; Corresponding Secretary, Dr. Edward E. Hicks; Recording Secretary, Dr. L. Howard Moss.

Lewis County Doctors Revise Fee Scale.—At a meeting of the Lewis County (Wash.) Medical Association in Centralia, October 13, resolutions were adopted increasing fees for nearly all kinds of services. Day calls inside the city limits are $3, night calls $5, and outside of the city a charge of $1 per mile will be added.

Nurses Form American Legion Post.—Nurses who served in the army and navy during the world war have formed a post known as the Jane Delano Post, in memory of the head of the nursing department of the American Red Cross, who died in France, and is buried near the hospital at Sevenay, France. Over two thousand nurses who saw service either at home or abroad are now eligible for membership. The place of meeting is the Central Club for Nurses at 132 East Forty-fifth Street, New York. At a preliminary meeting the following temporary officers were elected: *President*, Miss Grace P. Rogers; *First Vice-President*, Miss R. Lee Cromwell; *Second Vice-President*, Miss Christine M. Nuno; *Third Vice-President*, Miss Adele S. Poston; *Secretary*, Miss Anna S. Duncan; *Treasurer*, Miss G. R. Smith.

Charitable Gifts and Bequests.—Among the numerous beneficiaries of the will of Mrs. Margaret Olivia Sage, widow of the late Russell Sage, which disposes of a net estate of over forty-five million dollars, are the following. Woman's Hospital, New York, $1,578,172; Charity Organization Society, of New York, $1,573,172; Presbyterian Hospital, State Charities Aid Association, and New York Infirmary for Women and Children, each $776,586; New York Institute for Deaf and Dumb and Servants for the Relief of Incurable Cancer, $25,000 each.

To Improve Physical Condition of American Boys.—A conference of the United States Public Health Service was held on November 4 and 5 to discuss plans for launching a campaign to improve the physical condition of the 6,000,000 American boys between the ages of fifteen and twenty years. Representatives of the American Federation of Labor, the Y. M. C. A., and other organizations attended the conference.

Boston Dispensary Elects Officers. — At its 123d annual meeting, held November 21, the Boston Dispensary elected the following officers: *President*, James Jackson; *Board of Managers*, William Power Blodget, Ashton L. Carr, Charles M. Davenport, Mrs. Hilbert F. Day, Albert Greene Duncan, Miss Ellen F. Emerson, George A. Flynn, Mrs. Waldo E. Forbes, Edwin Farnham Greene, James Jackson, John R. Macomber, Robert W. Maynard, Frank W. Remick, Dr. Edward C. Streeter, Edward R. Warren, Stuart W. Webb, and Charles F. Weed.

Medical Society Elections.—The Medical Society of the County of New York, at its 114th annual meeting, held at the New York Academy of Medicine, November 24, elected the following officers for the ensuing years: *President*, Dr. Charles H. Chetwood; *First Vice-President*, Dr. George Gray Ward; *Second Vice-President*, Dr. Orrin S. Wightman; *Secretary*, Dr. Daniel S. Dougherty; *Assistant Secretary*, J. Milton Mabbott; *Treasurer*, Dr. James Pedersen; *Delegates*, Dr. Theodore H. Allen, Dr. Eden V. Dougherty, Dr. Daniel S. Dougherty, Dr. Gustav G. Fisch, Dr. Lewis F. Frissell, Dr. Ward B. Hoag, Dr. Samuel J. Kopetzky, Dr. George W. Kosmak, Dr. Eugene H. Pool, Dr. Abraham J. Rongy, Dr. Howard K. Taylor, Dr. Frederick T. Van Buren, and Dr. Orrin S. Wightman. Dr. Chetwood, the administration candidate for president, received 561 votes, and Dr. John Van Doren Young, an independent candidate, received 255 votes.

The Southern Medical Association, at its thirteenth annual meeting held at Asheville, N. C., November 12, 13, and 14, elected the following officers: *President*, Dr. E. H. Cary, Dallas, Texas; *First Vice-President*, Dr. H. H. Briggs, Asheville, N. C.; *Second Vice-President*, Dr. A. L. Gray, Richmond, Va. The other officers will be appointed by the executive committee. Louisville, Ky., was selected as the place of meeting for the next year.

Obituary Notes.—Dr. John J. Hayes of Boston, Mass., died at his home, November 18, at the age of 69. Dr. Hayes was born in Pembroke, Me. He was graduated from the Medical School of Boston University. He had practised in Boston for nearly twenty-five years.

Dr. Samuel Balash Childs of Brooklyn, a grad-

uate of New York University Medical College, in 1869, died after a prolonged illness on November 8, aged 76 years. He was for forty-five years in the service of the Faith Home for Incurables.

Dr. JOHN C. GRIEVES died at his home in Buckland, Mass., November 7, after a long illness.

Dr. JOHN MICHAEL STEPHEN died at Reading, Pa., on November 9 at the age of 64 years. He was graduated from Jefferson Medical College in the class of 1887.

Dr. NATHANIEL GILDERSLEEVE died at Lansdowne, Pa., on November 11, at the age of 48 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1900. He was professor of microbiology and bacteriopathology in the dental department of the university. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, of the American Medical Association, of the American Association of Pathologists and Bacteriologists, and of the Pathological Society of Philadelphia.

Dr. ALONZO L. HURD died at his home, Hartford, Conn., November 9, at the age of 61. He was graduated from the University of Vermont in 1891.

Dr. CHARLES P. HALLER died suddenly at his home in Bridgeport, Conn., November 9, in his forty-ninth year. He was graduated from the Hahnemann College in Philadelphia in 1902.

Dr. HENRY C. HOOD, of West Palm Beach, Fla., died as the result of an operation at the Emergencp Hospital, November 18. Dr. Hood was a graduate from the Long Island College Hospital in 1883.

DR. HIRAM HUNT, of Greenville, Me., died November 4, at the age of 59. He was graduated from Bowdoin Medical School in 1884.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Nov. 21, 1919.

Higher Birth-Rate in England and Wales.—The return of the Registrar-General for the third quarter of the year shows that there had been an increase in the birth-rate in England and Wales during that period. Births registered numbered 175,367, or 26,543 more than the total for the June quarter, and 6,916 more than that for the corresponding period of 1918. The rate was 18.5 per thousand of population, against 17.8 last year. Deaths numbered 89,112, and were 19,348 fewer than in the preceding quarter, and 25,106 below the total for the same period of 1918. The natural increase of population by excess of births over deaths was 86,255, against 95,872, 67,966 and 54,233 in the third quarters of 1916, 1917 and 1918, respectively. As regards marriages, statistics for the last quarter are not yet available, but in the three months ended on June 30, there was a large increase. The total number of persons married was 101,071, or 81,866 more than in the first quarter of the year, and 67,902 more than in the corresponding period of 1918. The rate of 21.6 per thousand is the highest recorded in the June quarter for several years. Infant mortality was equal to 70 per thousand, being 34 per thousand below the average in the ten preceding quarters, and the lowest recorded rate for any quarter of the year. In the United Kingdom 196,191 births and 145,912 deaths were registered in the three months ended June 30. The natural increase of population was therefore 50,279. The number of persons married in the United Kingdom during the quarter was 238,618.

Research Work in Industry.—It appears as if the manufacturers of Great Britain, or some of them at any rate, have learned the lesson that in order that industry may be on the highest plane it must be on a scientific basis. This is to say that scientific men, and chemists in particular, should be an essential part of the staff of industrial concerns. Germany appreciated this fact, as did America, and now Great Britain has awakened to its value. As an example of the tendency in this direction it may be noted that Dr. A. W. Crossley, Professor of Chemistry at King's College, London, has been appointed Director of Research to the British Cotton Industry Research Association. This appointment brings to mind the case of Sir Herbert Jackson, who had been the Daniell Professor of Chemistry at King's College since 1887, and who last year was made Director of the British Scientific Instrument Research Association. Sir Herbert Jackson's war-time researches conducted in the laboratories of King's College achieved the triumph of rediscovering the processes of manufacture of various kinds of glass previously made in Germany and Austria. Yet another instance is that of Mr. R. E. Slade, formerly junior lecturer in chemistry at University College, who had been appointed head of the British Photographic Association. Industry can afford to pay more for the services of scientific men it requires than universities. In existing circumstances the cost of living is so excessive that money is frequently a very weighty inducement. So far as the universities are concerned the situation is somewhat serious, but on the whole it is probably for the good of the country that these trained investigating brains should be used for the advancement of industry.

A Review of Naval Medicine.—On the evening of Monday, November 10, Surgeon Rear-Admiral Sir Robert Hill, Medical Director-General of the British Navy, gave the address as President of the War Section of the Royal Society of Medicine. The address consisted of a retrospect of naval medical conditions from the time of Nelson to that of Jellicoe, Beatty and Sturdee. The comparison drawn by the speaker between the casualties at Nelson's principal sea fights was instructive and pointed to the dead lines of modern naval warfare. In 1797 the Battle of Camperdown was fought. The British force numbered 8,221, the percentage of casualties being 10.03; 203 were killed and 622 wounded. At the Battle of the Nile, in 1798, the British force engaged consisted of 7,985 all told, the percentage of casualties being 11.22; 218 were killed and 678 wounded. At the Battle of Trafalgar in 1808, 17,772 British seamen and marines were engaged, the percentage of casualties being 9.51; 449 killed and 1,242 wounded. In 1916, at the Battle of Jutland, the number of men in the British Grand Fleet was in the neighborhood of 60,000, and the percentage of casualties was almost identical with that of the Battle of

the Nile, 11.14. The casualties were 6,688. But the evidence of the far greater deadlines of warfare in modern fighting ships is supplied by the striking fact that whereas in the Battle of the Nile and in all of Nelson's fights, the number of wounded greatly exceeded those killed, the figures of the Battle of Jutland were reversed; out of the 6,688 casualties there, more than 6,000 were killed or drowned, the number of the wounded amounting to only 674. It says much for the skill and care of the naval medical officer, and for the manner in which adequate means were provided for dealing with the wounded, that of 674 injured men but 74 died. The institution of a War Section of the Royal Society of Medicine is a new departure, but the attendance at the opening meeting and the interest taken in its success by the profession augurs well for its future. Sir Robert Hill in the course of his address sketched to some extent the evolution and development of naval medicine. In the time of Nelson the naval medicine and surgery were in a primitive condition, and frequently the captain of a ship or the admiral of a fleet took upon himself the role of medical adviser, and overriding the opinion of the surgeon, dispensed with generous hand any drug with which the ship or the fleet was most largely supplied, or toward which he was favorably prejudiced. One had only to read Tobias Smollet's account of his experiences as a surgeon on board ship before the era of medical naval medicine had dawned to learn that treatment was devoid of science and was distinctly rough and ready. It was indeed the case of the survival of the fittest in the days of Nelson and Smollet.

Progress of Medical Science.

The Boston Medical and Surgical Journal.

November 27, 1919, clxxxi, 22.

1. The Specific Treatment of Typhoid Fever. William Royal Stokes and H. W. Maldeis.
2. What is Influenza? George A. Soper.
3. Case Report: Transposition of Viscera, Tertiary Syphilis. C. Guy Lane.

1. The Specific Treatment of Typhoid Fever.—Stokes and Maldeis, after an extended review of the history of the specific treatment of typhoid fever, a discussion of non-specific treatment, and an outline of recent work, give personal observations in three series of cases. The first series consisted of 31 cases. The dosage used was 10,000,000 bacteria usually given subcutaneously at intervals of several days. The number of doses varied between one and six. These cases are mentioned merely to emphasize the opinion that no practical results were obtained by this small dosage, since the average duration of the disease was 30 days, and cases which even received the first dose on the second, third, and fourth days showed no tendency towards decrease in the duration of the disease. The mortality in these cases was 5, or 16.1 per cent. The next series, treated during 1913, consisted of about 60 cases. Doses beginning with 50,000,000 with an increase to 100,000,000 and 250,000,000 at intervals of several days were used. The duration of the disease was shortened in a fair number of cases, and some showed actual rapid decline of the temperature to normal after several doses had been given. The third series of 10 cases were treated, in 1916, by intravenous injections of a sensitized typhoid vaccine made from the Rawling's strain. Immune serum was added to the vaccine until agglutinins had all been saturated by the immune serum. Of these ten cases six were treated before the tenth day and were verified by blood cultures and the Widal reaction. Four cases were treated after the tenth day and showed only a positive Widal test, the blood cultures being negative. In five of the six early cases treated two injections were given at intervals of about four days and in three of these cases the disease seemed to be aborted. In two other cases the temperature gradually dropped to normal in about 18 days, and remained so. In the other early case only one injection was given and the case followed the regular typhoid course. Doses of 300,000,000 bacteria were given and the injection was followed by a slight chill and a rise in temperature of from 1 to 1½°, and no dangerous symptoms were noted. In the four late cases the Widal was positive but the blood culture was negative and the vaccine did no harm but no apparent benefit was derived from the treatment. Twenty-three cases were treated with a curative serum, prepared by injecting hogs with increasing doses of bouillon cultures of the typhoid bacillus. The serum had an agglutinative titer of 1—145,000. This serum protected guinea pigs against from four to five times the minimum fatal dose of the typhoid bacillus. The cases treated were in all stages of the disease with two deaths, one resulting from otitis media and the other from intestinal hemorrhage; 15 of the other 21 cases seemed to show favorable results from the use of the serum.

7. Surgery at a Base Hospital. Addison G. Brenizer.
8. Lethargic Encephalitis. Hyman Hershberg.

1. The Application of the Cardiovascular Studies of the War to Civil Practice.—John H. Musser, after enumerating the factors which account for the failure of the cardiovascular studies of the soldier and the inducted man before he actually was mustered into the service of the United States to yield as much information as have studies in other branches of internal medicine or in preventive medicine, points out some observations which will be of value in the future. He also gives a few personal observations made while acting as cardiovascular examiner of the thirty-eighth division, during which time 944 soldiers were referred for study on account of some objective disturbance of the cardiac mechanism, and while on duty in Base Hospital No. 20 in France. He excludes from consideration the complicating heart in the acute infections, pericardial or arterial lesions, and the value of the so-called test of cardiac function. The observations include: Congenital anomalies of heart; changes in size of heart; changes in impulse of heart; heart murmurs; cardiac rhythm and rate; and disordered action of the heart. During his examinations of the thirty-eighth division Musser saw three cases of dextrocardia, in none of which was there complete transposition of the viscera. Only one of the men was aware of his abnormality. He also saw three cases in which he thought there was congenital valvular disease. Cardiac hypertrophy is always secondary to some cause, and whenever an enlarged heart is found, the cause should be carefully sought. Changes in the size of the heart whereby the percussion dulness extends to the right of the sternum or upward above the third rib is indicative of damage to the musculature. The character of the cardiac impulse frequently gives a very definite clue as to the possibility of some abnormal heart lesion. Attention has been called (Goodman) to the value of the character of the impulse in differentiating aortic insufficiency and mitral stenosis when there is an apical thrill. Attention has also been directed (Morris and Friedlander) to a functional presystolic thrill. The outstanding feature in the examination of a large number of men is the frequency with which accidental murmurs are met. These murmurs may vary from simple cardiorespiratory murmurs, which disappear when the breath is held, to complicated puzzling murmurs, the genesis of which can be determined only by considering the auditory characteristics, the location, and the transmission

of the sound; changes in the area of cardiac dulness; changes in the character of the sound after exercise and after change in position, and the functional test of the heart. Another feature in physical examination which is frequently overlooked is that valvular lesions may exist without the occurrence of heart murmurs when the heart is auscultated in the usual upright position. In addition to the usual well known murmurs that occur in valvular heart disease a murmur which has the eponymous name of Graham-Steell has been much discussed. It is a diastolic murmur, heard best in the pulmonic area, replacing to a large extent the second sound, but may occur either at the beginning or ending of diastole. It is frequently heard only after exercise or with the patient in the prone position. The value of this murmur in prognosis is questionable. Among the unusual auscultatory findings may be noted the socalled apical click and the third heart sound. Both these phenomena are apparently normal, the first rare, the second quite common. Excepting the normal sinus arrhythmia that occurs in practically all healthy young adults, particularly after exercise sufficient to cause deep respirations, irregularities of the heart action in the young men who were submitted to physical examination were quite rare. The writer was impressed by the frequency with which cases of tachycardia were observed in the examinations in the thirty-eighth division. He attempted to classify etiologically the 424 cases that were referred to him with the diagnosis of tachycardia. The classification and number in each group were: 1. Myocardial, 69 cases; 2. hyperthyroid, 97 cases; 3. neurotic, 180 cases; 4. nervous (emotional), 28 cases; 5. toxic, 36 cases. The myocardial group included soldiers suffering from true myocardial insufficiency; group two, those with signs and symptoms of overfunctioning of the thyroid; group three, men with marked subjective and vague neurotic symptoms for the most part referred to the heart, presumably likely to develop disordered action of the heart; group four, those soldiers in whom the excitement of the examinations seemed to be the only cause of the increased heart rate; and fifth, the men in whom the tachycardia was attributed to intercurrent infections (not tuberculosis) or to overuse of tobacco and coffee. Tachycardia occurred in nearly all of the 1,200 men who had absorbed by inhalation a fair amount of gas. It persisted for weeks, in spite of the disappearance of all other objective symptoms. More intensive and more thorough work has been done in attempting to elucidate the pathogenesis of "soldiers' heart," "D. A. H.," "irritable heart," "effort syndrome," and "N. C. A.' or "neurocirculatory asthenia,' according to the varying nomenclature employed to describe a condition which was at all times essentially the same, no matter what name was applied to it. As a result of the extensive and varied study devoted to the subject, the conclusion has been reached, at least by Americans, that the soldiers suffering from disordered action of the heart were men who started with a certain constitutional inferiority. These men had a neuropsychic instability which in some cases was manifested before their induction into the service. In others an anxiety neurosis was apparently developed only when the men were sent to camp, while in still others the neurosis did not appear until they were actually engaged in the stress and strain of warfare. In other words, the condition was a neurosis developing in those men who were constitutionally weak, with sympathetic systems not under stable control. This syndrome is to be observed in civil as well as in military practice. The writer cited the case of a woman who complained of dyspnea upon the slightest exercise, associated with precordial pain, palpitation, and dizziness. The symptoms followed a rather severe psychic shock. In addition she had nocturnal dyspnea, some headache, was very nervous, had cold extremities, and flushes and sweats upon the slightest provocation. Physical examination showed nothing but a well marked tachycardia, greatly increased by exercise, and a faint systolic whiff at the apex. A comparable case in military practice is quoted.

2. The Treatment of Peritonitis.—George W. Crile bases the following scheme of treatment of abdominal infection, the most common danger incident to abdominal operations, on a total experience in all types of operations of his associates at Lakeside Hospital and himself, including 13,145 laparotomies among which are: 6,820 operations for appendicitis; 1,261 operations on the stomach and intestine; 1,289 gallbladder operations, and 2,837 operations on the female pelvic organs. By the general management outlined in this paper, their mortality in all abdominal operations has been decreased 33 1/3 per cent.; in acute appendix operations alone, the reduction in mortality has been 67.6 per cent. The essential points in the anociated treatment of abdominal infection, as stated, are: 1. Nitrous oxid-oxygen. 2. Anesthetized incision. 3. Accurate, clean-cut operation to diminish both infection and shock. 4. Adequate drainage. 5. Fowler's posture. 6. Vast hot packs over the entire abdomen, spreading well down over the sides. 7. Five per cent. sodium bicarbonate, with 5 per cent. glucose by rectal tap, continued as long as it is tolerated. 8. Primary lavage of the stomach, repeated only if indicated. (It will rarely be indicated if anociation is complete). 9. From 2,500 to 3,000 c.c. of physiologic sodium chlorid solution administered subcutaneously every twenty-four hours until the period of danger is past. 10. Morphin hypodermically until the respiratory rate is reduced to from 10 to 14 per minute, and held to this rate until danger is past. It should be noted, however, that morphin is not useful in a streptococcus peritonitis.

2. Some Considerations of Preventable Disease.—W. J. Simpson pointed out that the chronicles of knowledge recently acquired in tropical medicine and hygiene would involve, for the most part, a summary of the work done by the Fellows of the Society of Tropical Medicine and Hygiene. As ample evidence of the great bearing which exact knowledge, the outcome of scientific research, plays in the hands of sanitary administration, he mentioned the work done by Ross at Ismalia, in the Mauritius, and Greece, by Malcolm Watson in the Malay States, and by Gorgas in Havana and at the Panama Canal; and he pointed out that these results competed with the earlier results of the bacteriological or botanical era, when the etiology of infectious disease was first found to involve man's relationship with the lower animals, as well as with the vegetable world. Our ancestors attributed outbreaks of disease to an epidemic

constitution of the air and its influence on man's economy. That epidemic constitution has still to be studied. It has been lost sight of in recent years, though earlier it engaged the attention of philosophers who ascribed the origin and exceptional spread of epidemics to unusual meteorological conditions which caused floods drought, and famine. Who shall prove that they were wrong? What effect have floods, drought, and famine on the parasites of disease or on the various animal and vegetable microorganisms that teem in the soil? Do the parasites gain virulence and increased powers of diffusion in the soil or in the diseased vegetable world subjected to these conditions, or in the herbivorous animals that subsist on it, or in the vermin and insects that feed on the diseased animals and plants, or in man who, when famished, is glad to eat any vegetable, seed, grass, fruit, or meat, even if diseased? Apart from the virulence and diffusiveness gained by the sojourn of the microbe in one or several of these media, what are the factors which combine to form an endemic area for a predominant microbe? The geological nature of the soil often limits the geographical distribution and kind of animals living underground, and probably the kind of insects and microorganisms. It is in this direction that the explanation may be found concerning the endemic homes of cholera, plague, influenza, yellow fever, and cerebrospinal disease? Was Cunningham, of Calcutta, on the right track when investigating the nature and composition of the soil and its gaseous, organic, and inorganic contents? Is it the interaction of unusual metereological conditions on the local fauna and flora of certain limited areas, that prepares the microorganisms for the migration beyond their endemic homes—not by the air, as Bryden and others thought of cholera, but by making use of man, the lower animals and insects, and sometimes inanimate objects, as carriers? It is necessary to know more about the endemic areas of disease; they should be sought out and classified. It is there that the natural history of the disease in man can best be studied in relation to the geology, fauna, flora, and other conditions existing in the locality, and it is there that the conditions have to be investigated to give a clue to the factors which change a sporadic or endemic non-spreading or self-limiting disease into a diffusive and wide-spreading epidemic or pandemic. This knowledge will also allow us to adopt successful measures at the fountian-head. Endemic disease has now acquired greater diffiusing qualities because of the ample means for its transport and dissemination, supplied by the movements of commerce, labor, and emigration, while advancing and retreating armies, with their accompanying refugees, favor the spread in times of war. At these times, also, deficiency of food accentuates the conditions, and the longer the war lasts, and the larger its scale, the greater the effects must be, so that the trials of the five years just passed would possibly leave an aftermath of great epidemics. The speaker asked if it were a mere coincidence that the pandemic of influenza of the twentieth century, like that of the fourteenth century, was followed by widely spread manifestations of mental disorder, hysteria, and unbalanced judgment. He reminded his hearers that cholera and plague are now epidemic in Russia, that typhus and relapsing fever are spreading in Poland, and that smallpox is pervading the continent. War and epidemics bring out the weak spots in our armor of defence against disease, but their after-effect is generally to set men's minds actively in train to devise means for future protection and ideas and schemes that have for many years only created a languid interest suddenly get energized into activity and become a reality. This is seen to-day in the creation in England of a Ministry of Health, which has been advocated for 50 years but which the war and epidemic influenza has quickly brought into being. It is seen also in the determination to grapple with the housing question and other problems. Similar illustrations furnished by other wars were cited. Professor Simpson then traced the beginnings and progress of sanitary organization in India, closing with a plea for a broader view of tropical hygiene, and advocating an imperial health museum.

4. **On the Mechanism of Immunization, with Special Reference to Lipase.**—J. A. Shaw-Mackenzie recalls the fact that some years ago he suggested that the increase of tissue erepsin noted by Vernon in cases of cancer, as well as in tuberculosis and septicemia, might be a defensive response of the body. The same principle of a defensive mechanism underlies the well-known work of Abderhalden, whose facts have been confirmed in certain directions. During the past few years Shaw-Mackenzie's attention has been concerned with another enzyme, namely, lipase, the lipolytic or fat-splitting ferment, and he has suggested that it is an important factor in the defence of the body against cancer and bacterial invasion. A summary of these investigations is given. He was led to take up the question again on account of an article by Sir Almroth Wright (*The Lancet*, March 29, 1919, p. 516) on therapeutic immunization, in which no mention is made of any part that might be played by the fat-splitting enzyme. Shaw-Mackenzie believes that an important role in the treatment by autogenous vaccines whether injected into the tissues or intravenously. Vaccines and antitoxic sera *in vitro* increase the fat-splitting properties of pancreatic extracts in varying degree. Their action in this direction is less than that of serum, and their antitryptic power is small or absent. In the process of sterilization by heat the bacterial enzymes are destroyed, but even 100° C. is not destructive to the thermostable activating material which they contain. From this point of view part of the value of the vaccine must be due to this material, and its power to increase fat-splitting is a factor in its protective mechanism. In Sir Almroth Wright's method a donor's blood was immunised in vitro by an autogenous vaccine from the case, the serum was separated and transfused, with immediate success. Of all the sera thus obtained the serum of the blood portion which had been digested with 1,000 staphylococci per c.cm. gave the best bactericidal result when inoculated with a mixture of staphylococcus and the patient's own streptococcus. These statements led Shaw-Mackenzie to repeat his previous experiment, in which the addition of pancreatic coenzyme to serum appeared directly to produce the fat-splitting enzyme. The results obtained which confirm his former result with coenzyme, and the results of a few experiments made with the addition of vaccine to serum or blood, are given in a series of tables. These observations are summarized as follows: 1. The addition of pancreatic coenzyme and of vaccine to serum or blood in vitro exerts a lipolytic action. 2. The serum so treated has bactericidal properties. 3. The resulting tissue lipolysis in the case of vaccine appears in certain details to be different to pancreatic lipolysis. 4. Preliminary experiments indicate that serum (auto-serum) diluted and heated in which the coenzyme or coenzymes of the serum is present activates in a similar way the inactive prolipase of fresh serum. 5. In induced tissue lipolysis an explanation in part is afforded of natural and therapeutic immunization.

1. **A Few Surgical Lessons of the War.**—Major-General Sir Robert Jones, in an address delivered to the American College of Surgeons, devoted his attention chiefly to lessons learned during the war concerning the treatment of peripheral nerve injuries. The complications were such that it was often necessary to wait until they were overcome before any operation could be undertaken. Suppurating wounds, involving bones, muscles and tendons, and stiffness of joints, all delayed an attack upon the nerve. Muscles had to be freed and developed, and osteomyelitis drastically extirpated in order to render the muscles receptive to impulse. The sooner these complications were overcome or improved the better the chance for the nerve, not because delay in operating upon the nerve lessened the chance of regeneration, but because a chronic myositis very seriously impaired the power of the muscle to react when

recovery of the nerve path was re-established. Experience had taught that it was better to explore earlier and more frequently than was done at the beginning of the war. If a nerve is simply concussed or compressed, and has undergone Wallerian degeneration, it will early show signs of recovery. In cases which do not spontaneously recover in a month or two, it is usually a mistake to await regeneration of the nerve, and an exploratory operation should be undertaken. It is probable that no interval between wound and operation is too long to preclude possible recovery after suture. The state of the muscles, tendons, and joints is the important factor. It has been found that end-to-end suture can be attained in the great majority of cases by posturing the joints and by transposing nerves. In rare instances where the nerve could not be brought together it was found that this could be accomplished by a two-stage operation. The nerve should be approached through normal tissue above and below the lesion, and not through scar tissue. Nothing is to be gained from surrounding the suture line with vein or Cargile membrane or fat introduced from without. If the nerve has to be protected from scar tissue, a living muscular flap is indicated, but, whenever possible, the scar tissue should be freely excised. Nerve grafting has been followed, according to the investigations of the Medical Research Committee, with not one case of complete recovery and but very few partial recoveries, most cases ending in failure. Bridging by catgut, vein, alcoholized nerve, and other foreign material has consistently failed. The turning down of flaps of nerve, and nerve crossing or anastomosis invariably fails. End-to-end suture by one, or, if necessary, a two stage operation, is the method to be adopted in every case. In cases of irreparable damage to the musculo-spiral or posterior interosseous, tendon transplantation properly performed has proved an unqualified success. Paralysis of the anterior crural is very rare, probably because the femoral vessels are usually destroyed by the missile. There is here a choice of hamstrings to attach to the patella. In the one case encountered the recovery was sufficiently good to permit of climbing stairs with increasing power. The operation of tenodesis, suggested by Tilanus of Holland for flail feet in poliomyelitis, with modifications is helpful in drop-foot due to sciatic injury where suture is impossible. The prognosis as regards functional utility after nerve suture depends very largely upon which particular nerve has been injured. Thus the musculospiral usually makes a good recovery, while the ulnar, as regards the intrinsic muscles of the hand, does badly. The occupation of the patient is a factor of importnace in the prognosis. The after-treatment of cases of peripheral nerve injury has not undergone much change. The relaxation of the muscles is essential, and it is also necessary that the relaxed position of the nerve should not be too early dispensed with, otherwise the recently regenerated axis cylinders will be ruptured. Interrupted galvanic stimulation, massage, heat and re-education are indispensable desiderata. Concerning fractures Sir Robert Jones said the standardization of the Thomas splint, the education of men in its use, its application on the field of battle, secured for cases of fracture of the femur immobilization and simplified transport, it minimized shock, and it prevented the perforation of vessels by securing the alignment of the broken ends. Its use had to be understood from the field to the base hospital, for continuity of treatment was imperative. The reduction of mortality in fractures of the femur from 80 per cent. in 1916, to 20 per cent. in 1918, is attributable in part to this too long delayed recognition of the value of the Thomas splint, and to its distribution to the regimental aid posts. A subjugation of sepsis and gas gangrene also played an important part in these improved statistics, with all those accessories for the prevention and lessening of shock, such as the heated ambulance and the hot chambers. In addition to this the mobile expert teams which were rushed from place to place allowed of more skilled and frequent operative treatment. Then came the equipping of special femur hospitals, where some of the best and most inspiring war work was done. In this connection Sir Robert Jones referred particularly to the work of Colonel Pearson, who used the modified Thomas splint to permit of knee flexion, obtaining traction by the introduction of callipers which gripped but did not penetrate the femur, and using suspension of the Thomas ring and elevation of the femur. In addition he designed a special bed which rendered dressing easy and painless. In 300 cases of compound fracture treated in England in one of the special military surgical centers where this method of extension was employed, the average shortening was half an inch. The Thomas splint, with plaster or glue extension, is the ideal transport splint, and fractures of the femur, such as are met with in civil life, can be most adequately dealt with by this apparatus. Among numerous other points mentioned, attention may be called, finally, to the remarks concerning the restoration of function in joints. Forcible movements are rarely indicated. Certain symptoms following manipulation and passive movements indicating injurious strain are formulated. If pain occurs after manipulation and is of short duration, movements may be continued. If pain persists for lengthy periods after manipulation, *rest* is indicated. If the increased range of movement is maintained after manipulation, further movements can be safely prescribed. If in spite of movements, even in the absence of great pain, the range is continually diminishing, rest is indicated. The duration of pain when tissues are relaxed, rather than its intensity, should be our clinical guide. In overcoming adhesions and in subsequent manipulations the joint should be put through its various movements only once. The oft-repeated pump-handle movement applied at each sitting are never useful, and often start inflammatory symptoms. Voluntary movements can be safely allowed and should be encouraged. They are not followed by obstructive reaction.

4. On Acidosis.—A. D. Blackader lays no claim to original chemical or clinical research, but only to observations carried on in a few startling cases seen by him in consultation with other physicians, and a study of recent investigations by others, as reported for the most part in advanced scientific magazines. As now limited, the term acidosis is applied to conditions in which the reserve alkaline salts of the blood have been greatly diminished in amount. As a result of the various metabolic processes continually carried on in the living body there is a constant production, variable in amount and character, of acid radicles in the system. These are prevented from interfering to any extent with the normal alkalinity of the blood by the processes of oxidation, neutralization, and elimination, which, under the control of the regulating centers in the body, are in continuous activity. Despite these defences of nature, acidosis may develop in two well recognized conditions. The first and most notable of these conditions is such a serious disturbance of carbohydrate metabolism, of which diabetes is an excellent example, as may lead to the formation of an enormous excess of acid radicles in the system. These acid radicles make heavy demands on the alkaline reserve of the blood and call forth all the latent ammonia-producing power of the system. In such cases one generally finds an abnormal excess of nitrogen produced from the catabolism of the proteins, so that the amount of ammonia formed in defence of the alkali reserve is considerable. The percentage of urinary nitrogen eliminated under normal conditions in this form is small, not exceeding two or three per cent., but in diabetes, and in other conditions of disturbed carbohydrate metabolism, one finds

from ten to forty per cent. of nitrogen ordinarily excreted as urea now excreted as ammonia. Notwithstanding this great effort of the organism to save the amount of alkali reserve in the blood, all recognize the liability in diabetes to its depletion and to the appearance of the dreaded symptoms of acidosis and coma. The second condition in which acidosis may develop is nephritis, especially the chronic diffuse forms of nephritis in the adult and the severe acute forms of nephritis in children. The causes producing acidosis in nephritis, however, are quite different from those existing in the acidosis arising from a disturbance of carbohydrate metabolism. Symptoms of acidosis developing in nephritis are due almost entirely to a defective elimination of the acid phosphates, a condition met with chiefly in nephritis of the frankly parenchymatous type, and in the early stages of the chronic interstitial and arteriosclerotic forms, but which may also develop and become pronounced in uremia arising from any form. A similar condition is sometimes met with in children in whom, owing to a profuse watery diarrhea, or to a high fever with limited intake of water, the urinary output is greatly diminished. In both conditions the acid salts accumulate in the blood, its bicarbonate reserve and normal alkalinity is seriously diminished, and its hydrogen-ion concentration is increased. The lungs constitute a safety valve against this condition. The slightest increase of this hydrogen-ion content in the blood stimulates the respiratory center. In many cases nature's efforts at elimination restore the normal equilibrium. If, however, the hydrogen-ion concentration continues to rise in amount, the stimulation of the respiratory centre increases; the individual becomes gradually hypernœic, with the blood in his veins not cyanotic, but rather brighter than usual owing to the increased intake of oxygen, while the pulmonary alveolar air and the blood plasma both show, if examined, a marked diminution of the carbon dioxide tension. The clinical symptoms indicating this condition are deep pauseless respirations, gradually increasing in rapidity, associated with a stuporose condition gradually deepening into coma. A marked diminution of carbon dioxide in the alveolar air will now be found to exist. If at an early stage of this condition the alkali reserve in the plasma is restored by the administration of sodium bicarbonate in sufficient amounts, by mouth or, in severe cases, intraveneously, the symptoms rapidly subside; otherwise the hypernœa increases, and life terminates in a comatose condition. As a rule, increased pulmonary ventilation, as evidenced in deep, full, ceaseless breathing without cyanosis, and with no physical signs of obstruction to the entrance of air, always signifies acidosis. The most useful test, and at the same time a rational therapy, is determining the amount of sodium bicorbonate which will render the urine alkaline. In the normal five grammes dissolved in a tumblerful of water will change in the course of an hour or two the usual acid reaction of the urine to an alkaline one. In threatening acidosis the amount required to render the urine alkaline may often exceed this amount several fold. In every case of acidosis laboratory tests, when practicable, should be made. The occurrence of acidosis in the adult, excluding cases of diabetes, is infrequent. It is occasionally met with in some forms of nephritis, more rarely in some cases of rheumatic fever; in a few cases of pneumonia; in severe burns; and in surgical cases after hemorrhage and shock. It is met with more frequently in infancy and childhood, five such cases having been seen by the writer during the past three years. Attention is called in closing to the importance of recognizing the fact that in children acetone acidosis, sufficiently severe to cause death, may develop suddenly, apparently spontaneously; that mere starvation cannot be held responsible, and that some underlying and very obscure metabolic disturbance is thus far the only suggested cause.

Correspondenz-Blatt für Schweizer Aerzte.

September 11, 1919, xlix, 37.

Influenza-Like Bacilli as Pyogenic Organisms—Burchhardt, before the recent epidemic, found a hemoglobinophile bacillus which differed in no wise from the Pfeiffer germ. During the pandemic he was unable to find it. The few accounts in literature of pyogenic activities of the same germ are unsatisfactory. That is, in but few cases has it been shown by experiment to cause pus formation in pure culture. The author's cases were two in number and seen in January, 1918, when there was no epidemic influenza. One patient was a nursling with suppurative joints, while the other was an adult with pleurisy. The pus in these cases was free from blood, but in experimental disease in guinea pigs the germ possessed hemoglobinophilic properties. The germs grew on blood bouillon and caused hemorrhagic lesions. They were present in both cases in pure cultures. During the epidemic there were scattered finds reported by authors, especially in small children, in which there were joint lesions of the type mentioned. The incidence was sporadic at times—that is, there were no other cases in the family. The diagnosis of septic infection is recorded or, in other words, the influenzal nature was not recognized. In certain cases meningitis was also present. Some reports state that Pfeiffer's bacillus was found in the pus, while in others the identity of the germ is left undecided. While in clinical influenza Pfeiffer's bacillus is not found in the blood in some cases, apparently the same organism with hemoglobinophile properties has been recognized in that location even in the years following its first recognition. Thus in 1907 Meunier found in four fatal cases of bronchopneumonia in infants the Pfeiffer organism in the blood and by inoculating its cultures into animals produced septicemia. The question of identity of this germ with Pfeiffer's bacillus must still be left open.

Annales de Gynécologie et d'Obstetrique.

September, 1919.

Male Hermaphrodite with Uterus and Tubes.—Couvelaire and Duclaux report the case of so-called tubular male hermaphrodism. The subject was a soldier who presented no female secondary sexual characteristics, while his external organs were masculine. He was married and had two children and his condition would never have been suspected had it not been for a hernia operation. The hernia was a left inguinal which dated from the age of 16 or 17. It had become inguinoscrotal and the scrotum alongside of two apparent gonads contained a hard irreducible object. When the sac was incised a uterus was found with tubes and uterine ligaments. The gonads were therefore regarded as ovaries. No other sac contents are mentioned. The uterus was extirpated with the tubes and ligaments. The right gonad was at once removed and proved to be a testicle. The left was allowed to remain to "give the illusion of a testicle." The radical Bassini operation was then performed to cure the hernia. The subject had but a weak sexual appetite and had never copulated until his marriage. The ablated testicle was very small, partly because an epididymis was absent. The gonad left behind was larger and in the accompanying photograph appears to be of nearly normal size. The authors neglect to describe it. To clear up the sex beyond doubt the subject upon request masturbated before the medical men and his semen was thin with but few spermatozoids and these not very lively.

Natality, Morbidity and Mortality of French Children in Regions Occupied by the Teutons.—Calmette writes of this subject as something to be ascertained in due time. At present we have but few data to quote. In the small town of Orchies, with 5000 inhabitants in time of peace, there was methodical destruction, house by house, the Hun making use for this purpose of Ostwald's famous incendiary pastilles invented for the special purpose. The inhabitants fled and we have no idea as yet of their lot. It is the same with St. Quentin, Douai, Cambrai, Valenciennes, etc. It has been estimated that 5 per cent. of the total population perished, but of the child contingent we know nothing. In Lille the number of births in 1913 was 4885 and in 1914, 4541. In 1915 the number was reduced to 2154 and for the next three years was between 600 and 700 annually. This means a loss in births of 15,000. Of over 18,000 school children of Lille at the time of the armistice 8000 have required hospitalisation or removal to convalescent colonies as a result of the hardships of war.—*Le Bulletin Médical.*

Society Reports.

THE AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-sixth Annual Meeting, Held at Atlantic City, June 14, 16 and 17, 1919.

THE PRESIDENT, DR. GUY HINSDALE OF HOT SPRINGS, VA., IN THE CHAIR.

(*Continued from page* 944.)

Radiographic Changes Seen in Influenza Pneumonia.—Lieut.-Col. ESTES NICHOLS, U. S. Army, of Portland, Me., presented this communication, the result of a study of influenza from a radiological standpoint at United States Army General Hospital No. 16, where they had a thoroughly equipped *x*-ray department under the direction of Major James Honein. The radiographic examination of the very sick patients was possible because of the bedside *x*-ray apparatus which enabled them to do a routine *x*-ray examination on very sick patients with very little disturbance to them. In the radiographs of the influenza cases there was a general increase of density throughout the lungs, this density being best described as hazy or smoky in character. This generalized density usually extended from apex to base, the inner half, especially adjacent to the mediastinal border, being most marked. The most marked changes were seen in the bronchial structures themselves. Peribronchial thickening was seen most marked around the hilus, extending outward in a "sunburst" type and rapidly diminishing in size from the hilus to about the outer one-third of the lung. This was more marked on the right than on the left, partly because the left was obscured by the heart. A large number of cases of marked bronchitis or bronchopneumonia occurred at the right base. In cases in which influenza progressed toward recovery, there was a general diminution, first, in the hazy density and then in the diffuse density of the bronchial structure. The density around the hilus was partly due to peribronchial thickening and remained considerably longer. The hilus became affected very early and in no case was there any question as to this reaction at the hilus. The heart showed a dilatation of the right auricle and a slight dilatation of the pulmonic area, but the heart as a whole was not much enlarged in influenza. Unilateral congestion was seen in a few cases, which invariably recovered in a few days. They all showed that the lower bronchial structure and the bronchi of large diameters were earlier and more markedly affected than the smaller and terminal branches. There was a diminution of pulmonary function as evidenced by the height and shape of the diaphragm, which became much more dome-shaped than was commonly the case. This was true in most cases. The appearances to be looked for in bronchopneumonia were first those described under influenza which were apparently of a bronchial nature. There seemed to be a diffuse peribronchial thickening so that the individual outlines of the bronchi could be seen with difficulty. This was shown as extending through the hilus, outward and downward in most cases, and there might be localized areas in which the bronchial outline resembled somewhat the "pussy willow" stage, like the budding of a willow branch seen in spring. The next distinct stage was a spreading out of these areas to a point of confluence of more or less localized areas. In these areas the congestion appeared light and hazy. There were a few instances in which resolution began in this stage, but in the majority of cases as the process progressed the density increased, the detailed structure became obscured, and a pseudo lobar pneumonia appearance might be seen. Frequently after one portion of the lung had become consolidated the next earliest change was seen on the opposite side, extending outward from the hilus. Consolidation occurred most often in the lower right lobe, just medial to the lower angle of the scapula. The next most frequently affected was the lower left lobe, then the right upper, and middle lobes, and finally the left upper lobe. Associated with the early bronchial changes were the marked changes of the hilus on the side where the bronchial pulmonary changes began. In the marked changes of bilateral pneumonia where the greater part of both lungs was affected, the bases became so dense that a differential diagnosis between an extensive edema, pleural effusion, and pneumonia could not be made. Two associated changes occurred very early in the onset of pneumonia. Invariably as early as the changes occurred in the hilus there was seen marked acute dilatation of the right auricle and also marked dilatation of the pulmonic areas. In a considerable number of cases dilatation of the aorta also occurred. In a few cases dilatation of the left ventricle occurred. The second associated change had to do with the position and shape of the diaphragm. In the majority of cases the diaphragm on the side first affected became more dome-shaped and its position one or two interspaces higher than normal. This occurred so constantly that it was one of the diagnostic features of the disease. In massive types of pneumonia the diaphragm was often lower than usual. Leucopenia was found with bronchopneumonia and leucocytosis was generally found with lobar pneumonia. In a few cases a pleural reaction was demonstrated, shown by congestion and thickening of the pleura in the interlobar fissure. In many cases that recovered there was a persistence of the congestion of the hilus and mediastinum. The appearance of tuberculosis with influenza was exceedingly difficult to make out unless the tuberculous lesions were ancient ones and not of recent activity.

Treatment of Influenza and Its Pulmonary Complications.—Dr. JAMES N. ANDERS of Philadelphia read this paper. (See MEDICAL RECORD, August 9, 1919, p. 223.)

Some Historical Notes on Early Epidemics of Influenza in America.—Dr. GUY HINSDALE of Hot Springs, Va., presented this communication and read excerpts from some of the descriptions of influenza published by authors of those periods. Among these was a passage from a description of the disease by Hubbard under date of 1647 in which he informed us: "In 1647 an epidemic sickness passed through the whole country affecting the colonists and natives, English, French, and Dutch. It began with a cold and in many was accompanied by a slight fever, etc. It extended through the plantations in America and in the West Indies. There died in Barbados and St. Kitts, five or six thousand each." Noah Webster, in his "Brief History of Epidemic and Pestilential Diseases" published in Hartford, Conn., in 1799, gave in chronological order a list of epidemics of influenza or "epidemic catarrh" dating in Europe from A. D. 1174, and in America from 1647. In this remarkable list of forty-four instances of influenza epidemics most interesting references were made to volcanic eruptions, earthquakes, and comets, since it was the custom of those days to associate something supernatural with the outbreak of a pestilence. An effort was also made by these observers to trace a connection between the occurrence of these epidemics and the season, it being noted that most of them happened after or during severe cold or during moist weather, in the spring, winter, or autumn. Dr. Hinsdale read Dr. Benjamin Rush's description of an epidemic of influenza occurring in 1790 which revealed a close parallel between that and the recent one. The epidemic of 1918-19 seemed, however, to have exceeded any previous one of which there was a record. The London *Times* had stated that the deaths in the entire world had numbered six millions. It was estimated by the Bureau of Census that in the United States the deaths in this epidemic, including influenza and pneumonia, had reached 700,000. A third epidemic of influenza occurred in the United States twenty-seven years after the one Dr. Rush described, and was referred to by Daniel Drake in his "Systematic Treatise on the Principal Diseases of the Interior Valley of North America." It was noted in this description that Drake was acting as an army surgeon to two regiments of militia in camp when the influenza swept from the East to the frontier post in the Ohio Valley where he was stationed. Dr. Drake closed his account by noting among the sequels of influenza the occurrence of purulent pleural effusions and the unusual number of cases of pulmonary phthisis that developed. In commenting on these records, Dr. Hinsdale said it was worthy of record that the epidemic of influenza that ravaged the

Atlantic seaboard shortly after the Revolution had practically all the features of the present outbreak. One was struck with the very remarkable parallel between the course of the epidemic of 1790 and that of 1918.

Dr. J. N. Hall of Denver said he had pathological knowledge supplementing Dr. Daland's paper. In many of the hospitals of the South very extensive nasal hemorrhages took place necessitating packing, and in some instances there were hemorrhages from the bowels. There was every reason to believe that these hemorrhages took place in connection with the onset of influenza. In several instances coming under his observation there was reason to believe that there was hemorrhage from the adrenals, as the patients showed a condition of shock and low blood pressure. In a good many cases dying of pneumonia hemorrhages were found scattered through the adrenals. Another point of more than ordinary interest was that in examining about 100 old gassed cases in a dozen camps it was found that these cases gave a definite picture just as did the influenza and pneumonia cases. There was a characteristic tenting of the diaphragm in 15 or 20 per cent. of the badly gassed cases and the chronic cases showed adhesions and calcified glands and there might be a collapsed bit of old bronchitic lung distinctly different from what was found in influenza and pneumonia.

Dr. John B. Hawes of Boston said that in Massachusetts among 1,000 tuberculous cases the incidence of influenza was six per cent. and in 5,000 other institutional cases the incidence of influenza was 30 per cent. The interesting question was whether it was a fact that the tuberculous individual had developed a certain amount of immunity against other infectious diseases, or was the fact that so many escaped influenza due to other hygienic measures such as washing the hands, caring for the teeth, etc., which were practised more carefully by tuberculous patients than by others.

Dr. Robert Childs Patterson of Saranac Lake, N. Y., said that personally he had looked at this relative immunity of the tuberculous to influenza as due to several causes. The tuberculous patient lived out of doors and was therefore less exposed and he came in contact with other persons to a less extent than did others. Then prophylaxis of the mouth was very important in limiting the effects of complicating infections. Again, the tuberculous patient if he felt ill was so frightened that he went to bed and stayed there and thus suffered less from a mild influenzal infection than did others. He did not believe that the tuberculous patient had any specific immunity against other infections.

Lieut. Col. J. H. Elliott of Toronto said that in their hospital the entire staff had influenza and the patients escaped. He said he wished Dr. Daland would tell them something of the after history of those cases suffering from deranged mental conditions. He had been told that their prognosis was good, but he knew of a number of cases still in the hospitals. Speaking of alopecia in connection with influenza, he said that this condition had been most intense in Toronto but they found that the hair came in again. The historical side of influenza as presented by Dr. Hinsdale was very interesting. It seemed from what could be learned of the history of former epidemics that they were almost exactly like the recent one.

Dr. A. G. Shortle of Albuquerque, N. M., said that his assistants had under their care two or three hundred tuberculous patients and while many had influenza and some had pneumonia, only three died, and these were patients who had collapsed lungs following artificial pneumothorax. He thought that the fact the tuberculous patient was fighting a fixed infection gave him a certain amount of immunity against other infections.

Dr. Robert Wilson, Jr., of Charleston, S. C., said that the opinion was expressed that the epidemic stopped because the susceptible material was exhausted. He knew of a military school where there were about 200 boarders and a number of day pupils. When the influenza broke out the day pupils were kept out of the school. In ten days or two weeks the epidemic expended itself, after they had had about 100 cases. In January there was a recrudescence and only the day pupils contracted the disease. As to the immunity conferred by one attack, it was rather singular that the epidemic of 1833 was followed by another similar epidemic in 1837, while the epidemic of 1889 was not followed by a similar one until the present epidemic occurred. From this it would seem that in the earlier epidemic immunity lasted only four years while in the epidemic of 1889 immunity has existed for a much longer period.

Dr. H. L. Barnes of Wallum Lake, R. I., said that at their place as many as 40 per cent. of tuberculous patients were infected in some of the wards and they had a death rate as high as 30 per cent. However, in the hospital for advanced cases of tuberculosis there were only a few cases of influenza and hence they had concluded that advanced cases of tuberculosis had a certain immunity to influenza.

Major W. L. Dunn, speaking of his experience with influenza on the Italian front said that one of the things that struck them was that they were dealing with a condition in which bronchopneumonia was almost the rule, so they treated all cases from the first as though they had pneumonia. A striking feature in these cases was a toxic myocarditis. Their cases were treated by no special method but as they were without coal and for two months without heat, they kept the windows open so that the patients had plenty of fresh air. They were also given plenty of water and were kept in bed from the beginning. Their mortality from pneumonia among several hundred cases was 3.72 per cent., while the mortality from influenza was 1.83 per cent. Though the infection in that area was of a rather mild type they had a lower mortality rate than other hospitals in that locality.

Lieut. Com. Judson Daland of Philadelphia said that in reference to tuberculous patients having a relative immunity to influenza, it was possible to get a certain degree of immunity by means of other organisms, as the streptococcus, staphylococcus, pneumococcus, etc. It might be well to bear this in mind and to use vaccines against these secondary invaders that were usually responsible for the fatal termination following influenza. In other words, the vaccines of the streptococcus, staphylococcus, and pneumococcus and other organisms that caused death. An interesting fact in his experience at Hog Island was that digitalis did not produce the good effect in influenza that it did in other conditions. The occurrence of epistaxis was very common. In reference to the question in regard to mental conditions, their men were all carefully picked and they had no men with unstable nerves. As to the alopecia, they had no females, so this condition was not noticed. As to the period of immunity, experimental work with induced influenza seemed to show that the duration of immunity was not much longer than two months, but he could not say definitely how long immunity lasted.

Dr. J. M. Anders of Philadelphia said that he had said about all he wished to say in the paper. He felt convinced that this epidemic of influenza did not differ from other epidemics. In other epidemics it had always been true that children and older people were relatively immune. The period of susceptibility in all epidemics was from 18 to 35 years. Some one had raised the question of the hair falling out. In many severe cases that survived the hair was lost but it came in again. Dr. Anders stated that he had forgotten to mention one preventive measure and that was the washing of the hands. The Board of Health of Philadelphia issued a bulletin to the people advising washing of the hands and calling attention to the fact that mouth infection was probably the most common road of dissemination. Speaking of the unsatisfactory effect of cardiac stimulants in the recent epidemic he emphasized that he had used camphor in sterile oil with most satisfactory result and he felt that it certainly benefited the heart when other things failed. From the course of these influenza epidemics it seemed that the duration of immunity must be brief. It looked as though it might be from ten weeks to three or four months.

Myasthenia Gravis; Its Probable Causes and Treatment; Report of an Unusual Case.—Major W. D. Alsever, U. S. Army, of Syracuse, N. Y., stated that

myasthenia gravis was a rare disease marked by paresis and rapid tiring, with lymphocytic infiltration in muscles and other tissues. He related in detail the history of a patient in whom there could be little doubt as to the diagnosis, inasmuch as in this case a chronic paresis, rapid tiring of muscles, variation in intensity of symptoms, and the myasthenic reaction were present, while fibrillation, muscular atrophy, reaction of degeneration, sensory symptoms, and loss of sphincter control were absent. This case was of interest because of its long duration, since 1914, and because of the striking contrast between the severity and duration of the last relapse and the present good condition of the patient. In 1917 this patient nearly choked to death many times and his feeble, emaciated condition with his inability to swallow food made the prognosis very grave. At present he was fully nourished, fairly strong, but tired easily. In commenting on this case the writer said that the cause of myasthenia gravis had long been sought, and he reviewed some of the theories advanced to explain the condition. Abnormal function of some endocrine gland had been suggested as a cause, but at present it could neither be proven nor disproven. Similarly it was possible that toxemia originating outside the endocrine glands might be the cause. The association of abscesses in the teeth with the onset of myasthenia in this case was suggestive. That myasthenia gravis was not a pure neurosis was shown by the almost constant finding of widely distributed lymphocytic infiltrations. That it was not dependent on a familial defect in the nervous system was indicated by McCarthy's report that, among his 182 collected cases, only 20 per cent. gave a history of any sort of nervous disease in the family. Bodazzi made the interesting suggestion that there were two sorts of contractile substance in the muscle, a fibrillar which contracted quickly and a protoplasmic which contracted slowly, and that a selective poison reducing the excitability of the protoplasmic substance would produce the symptoms of myasthenia gravis. However, the physiological basis for this theory had not been established. In the case here reported the somewhat neurotic temperament and the unusual mental and physical strain at the onset of the ptosis established the foundation for a neurosis. The "heart weakness" of twenty years before, which probably was transient hyperthyroidism, made disturbance of the internal secretions seem probable, while the abscesses in the teeth suggested still another source of toxemia. Malignant disease was not probable for the sickness had now lasted over four years, two years ago a fatal outcome seemed imminent and now the patient was able to work again. The *x*-ray showed dulness and opacity in the sternal region which might be due to enlargement of the thymus, but proof of this supposition was lacking. There was no curative treatment for myasthenia gravis. Good nutrition was important and at no time was this appreciated so much as during a relapse when swallowing was difficult. The writer's experience with this case had led him to have profound respect for the ability of rest to control the disease. Each relapse had followed a period when the patient allowed himself repeatedly to work to the point of extreme fatigue. If he rested as soon as he was conscious of increasing weakness his improvement was usually surprisingly prompt. While rest was not curative, it seemed that the careful avoidance of fatigue would make the life of such patients more comfortable and relapse less probable.

Some Lessons of the War in Pulmonary Tuberculosis.—Dr. Gerald B. Webb of Colorado Springs read this paper in which he said that it was too early to draw definite conclusions from the war regarding pulmonary tuberculosis, yet certain incidents connected with this disease in our army suggested lessons which might be considered. These lessons related to the diagnosis, the prevalance of tubercle infection, and the hygienic prophylaxis of tuberculosis. A review of the statistics made it evident that our experts erred on the side of making a positive diagnosis more than three times as frequently as they should have done. In spite of this over-zeal, there had been more than 1,200 deaths from pulmonary tuberculosis, and 8,500 patients had been admitted to army tuberculosis hospitals. At present the death rate from this disease was heading the weekly mortality returns in our army. In addition over 1,200 cases were being studied in the first two million men who had been demobilized. From the work of these examinations two conclusions might be drawn: first, too many men were diagnosed as tuberculous; second, it was impossible to detect the men who in the first few months would break down with this disease. Statistics and evidence of this were adduced from the statements of authorities both in England, France, and the United States. The errors in the diagnosis of pulmonary tuberculosis admitted to our free observation centers in France were in order of frequency: pneumonias of delayed convalescence; the bronchitides, frequently complicated with nasal sinus infections; gastrointestinal conditions with loss of weight, cough, asthenia, etc.; hyperthyroidism; psychoneurosis, including effort syndrome; syphilis of lung and new growth; bronchitis due to Klebs-Loeffler bacillus. Streptothrix conditions were not found. Neither mustard gas nor excessive cigarette smoking appeared to precipitate cases of pulmonary tuberculosis although both would cause mistakes in diagnosis. Following the mild epidemic of influenza of April and May, 1918, and the more severe epidemic of September and October, 1918, a decided increase in the numbers of positive cases of tuberculosis occurred. Trauma and gunshot wounds of the chest did not appear to bring about the development of this disease. Over-fatigue of certain divisions usually resulted in an increase in the number of cases of pulmonary tuberculosis coming from those divisions. Pleurisy with effusion was rare; only 9 per per cent. of the first 700 soldiers returned to the United States as tuberculous gave a history at some time of pleurisy with effusion. They received the impression that very many of these pleurisy cases were not tuberculous in origin. In some streptococci were found in the fluid removed. It was exceptionally rare to find a tuberculous deposit in the lung opposite to that affected. A remarkable opportunity was offered in the American Expeditionary Forces for the investigation of tubercle deposits in the bodies which came to autopsy. Unfortunately few pathologists were found who were thoroughly alive to this opportunity. A review of the observations made by the most interested pathologists at the tuberculosis meeting of the Research Society of the American Red Cross in Paris last November of the work of Major D. J. Glomsett, Major H. E. Robertson, Captain A. N. Desjardins, and Col. Sir Almroth Wright seemed to justify the conclusion that a much smaller percentage of our young adults might have deposits of tubercle than we had been led to suppose. It had been considered heretofore that 75 per cent. and up of our fellow beings were infected with tubercle. Such infection had been considered a protection against the development of pulmonary tuberculosis. From the pathological findings quoted it would seem that instead of 75 per cent. of young adults being protected through early deposits of tubercle, possibly 75 per cent. were without such protection and so would be vulnerable to infection. The careful combing of our camps of all cases of tuberculosis carriers would minimize the infection with this disease under the conditions of mobilization. Had some of our men, therefore, contracted the disease while abroad? They kept careful tabulations of the home centers of these tuberculous soldiers, and strange to say, they had returned more tuberculous soldiers from Texas than from Pennsylvania, and more from Kentucky than from Massachusetts. In general the larger proportion were from agricultural States and farmers headed the list of occupations. It was this same element that, as would be remembered, succumbed so readily to measles and pneumonias in the cantonments. Von Pirquet tests had been known, for some time to yield fewer positive reactions in country districts than similar tests made in the cities. The opportunity for infection was known to bear a direct ratio to the density of population. About 500 soldiers died in France of a rapid form of tuberculosis. Twice as many of the 700 cases reported came from the service of supply where men were distributed in cities and villages as from the front. Fourteen per cent. of these returned cases were negroes, whereas, possibly not five per cent. of the troops were colored. The negro mortality from tuberculosis at the age of twenty-five was figured in

civil life as being five times greater than that of the white. It was the complaint in all the armies that when men were discovered with this disease they were in an advanced condition. In speaking of the hygienic prophylaxis the writer stated that it had been well said that the enjoyment and the employment of fresh air was not instinctive to the human race. It had been a revelation to see that this, probably the most important prophylactic measure we had, was so generally ignored. The men huddled around stoves in shut tents in Texas, stuffed their clothes in ventilators and port holes on transports. Nurse and ward masters kept their wards so stuffy that to those who worked outdoors the atmosphere of tuberculosis shelters and barracks resembled that of monkey houses. Medical officers of exalted rank slept with hermitically closed windows, and lastly many of the Army of Occupation housed in comfort in Germany were sleeping and living with closed windows. Surely the campaign for fresh air had fallen on deaf ears and needed new activation. Splendid food and good warm clothes all our soldiers had, yet they avoided fresh air carefully.

Col. GEORGE E. BUSHNELL of Washington, D. C., said it seemed to him that the idea expressed was that the cases which did not show old anatomical lesions were primary cases of tuberculosis. If one used the expression primary case, that would mean that the men had never come into contact with tubercle bacilli; he thought that was extremely improbable. It should be remembered that the men were carefully combed over by the draft boards and those that had lesions were eliminated, so that they were dealing with a selected class of men and the results were not comparable to the general population. It had been observed that men of the athletic type if they got tuberculosis frequently got the acute type of the disease, and that in athletic people this was probably the result of not having come in contact with the disease. This was in line with what had been observed when large numbers of tropical natives were herded together and exposed to tuberculosis for the first time. They got the acute type of the disease with a very high mortality. If a man was truly susceptible and was exposed he would get the disease in the acute form, but he thought in the majority of cases there had been a previous infection probably of the glands with no lesion in the lungs at the time the man was examined by the draft boards. There was certainly no epidemic of tuberculosis in the army. Among the 2,131,000 men the death from tuberculosis up to May 1, 1919, numbered only 1,220, that was 525 per million men and that was a small mortality all things considered.

Dr. FRANCIS M. POTTENGER of Monrovia, Cal., said that Colonel Bushnell had pointed out the key to the situation. One might have a very small focus or no focus in the lungs and enormously enlarged glands. This was frequently the point of implantation and it was here that the fight against the disease went on. He did not believe that the acute type of infection seen in the army were new infections for it was almost impossible that these men had not come into contact with the tubercle bacilli. The danger of infection from one adult to another was extremely slight and this was an important point on account of phthisophobia. Most adults had had previous infection. If one took an advanced case of tuberculosis an enormous amount of immunity was found to have developed. Millions of tubercle bacilli passed over the mucous membranes without causing infection. Dr. Pottenger stated that he had had a great many rejects referred to him by the draft boards and he found that tuberculosis was diagnosed probably three times as often as it actually existed. One should be careful in drawing conclusions from selected groups of men and applying them to the general population.

Dr. WEBB, in closing, said the evidence in favor of primary infections was the fact that these men were many of them from the country; if they had come from the city it would have been entirely different and they would have been much more likely to have harbored early infections. The pathologists who had made the examinations had not forgotten to examine the lymph nodes.

Points of Differential Diagnostic Value in Pulmonary Abscess, Bronchiectasis, and Pulmonary Tuberculosis, with an Explanation of the Cause of the Difference in Auscultatory Findings.—Dr. FRANCIS MARION POTTENGER of Monrovia, Cal., read this paper in which he stated that a careful study of the clinical history would often aid in the differentiation of these processes. Cavity formation in tuberculosis was more apt to be preceded by repeated attacks of toxemia, sometimes months apart, while pulmonary abscess usually came on promptly following an acute infection in a patient who was previously in good health. He had seen a few cases of tuberculous abscess form in which the patient had complained of acute illness for only a short time. The patient with tuberculosis as compared with the one suffering from pulmonary abscess or bronchiectasis was more apt to suffer from nerve irritability, and as a rule showed a greater degree of nutritional disturbance when the acute process came on. Repeated attacks of bronchitis were common in bronchiectasis and in tuberculosis, but not in pulmonary abscess. Pulmonary abscess was a disease caused by microorganisms which produced acute infections. These organisms were often found in the air passages as was the case during epidemics of acute respiratory disease. Where the abscess followed operation on the upper respiratory tract the bacteria were probably lodged in large numbers and aspirated directly into the trachea and bronchi. They were capable of ready implantation and rapid multiplication. They followed the direction of the strongest air currents with greatest ease and usually produced their infection in the lower lobes. Less often they were found in the upper lobes. Blood metastases must also be considered. Bronchiectasis, being a disease of the bronchi in which dilatation and distortion occurred as a result of pathological changes in their walls, often followed fibrosis and contraction of pulmonary tissue. It was commonly found near the hilus although the affection might involve the bronchi in all parts of the lungs. Pulmonary tuberculosis, being a chronic infection resulting from microorganisms which were not commonly found in the air passages of those who were not suffering from tuberculosis, and which required time for multiplication, was not a disease which resulted immediately on the bacteria gaining access to the air passages. The tubercle bacilli, after entering the tissues, passed readily to and settled in the lymphatic glands, and were later carried through the lymph stream to be deposited in the capillaries or lymph spaces of the pulmonary tissue. While implantation of the microorganisms which produced acute infections was favored by the relatively greater motion and greater force of the air currents in the lower lobes of the lungs which forced the bacteria deeper into the tissues, the relatively lessened motion of the apex favored implantation of the slowly developing, blood and lymph borne tubercle bacilli; consequently active tuberculosis with cavity formation was usually found near the apices, while pulmonary abscess was usually found in the lower lobes, and bronchiectasis might be found in any portion, but often affecting the large bronchi near the hilus. On careful inspection a diminution of motion would nearly always be noted on the side of the involvement in all these affections. In pulmonary tuberculosis this might be difficult to ascertain in those instances where there was a lesion in both lungs. In bronchiectasis, the lung involved was practically always contracted and the mediastinum shifted toward that side. In pulmonary abscess contraction with shifting of the diaphragm might or might not take place, although it usually did if the process was a chronic one. The same was true of tuberculosis. Reflex changes in muscles and degeneration of the soft tissues—skin, subcutaneous tissue, and muscle—was as a rule not marked in pulmonary abscess and bronchiectasis as it was in pulmonary tuberculosis. Chronic tuberculosis of the lung might be suspected whenever the neck muscles and the subcutaneous tissue and skin of the neck and chest above the second rib anteriorly and the spine of the scapula posteriorly were markedly degenerated. Pulmonary abscess and bronchiectasis also caused degeneration in these same tissues, but as a rule it was not so extensive, and in some instances of these affections practically no reflex trophic changes occurred. Speaking of the signs elicited by auscultation, Dr. Pottenger said that pulmonary tuberculosis

might be suspected in cases giving a definite history of cough and expectoration, usually a fairly large quantity, and comparatively few signs of moisture on auscultation. If the examiner could form a true conception of why there were marked changes on auscultation in pulmonary tuberculosis, and why with even larger quantities of sputum, as was often the case, there was such an absence of changes on auscultation, in pulmonary abscess and bronchiectasis, then the differentiation of these affections would be easier. The explanation of this fact was based on the difference in pathology. Conditions which favored the production of the most constant and greatest quantity of pulmonary râles were not found in the cavity itself but in the surrounding tissue as noted in pulmonary tuberculosis. A history of persistent expectoration of moderate or large quantities of sputum, with a diminished expiratory excursion on one side of the chest, and an absence of paucity of crepitations or mucous râles on auscultation over the side affected should make one think of pulmonary abscess or bronchiectasis.

Internal Medicine as Observed at a Base Hospital in France.—Lieut. Col. GEORGE MORRIS PIERSOL of Philadelphia presented this paper, in which he declared that the accomplishments of the surgeons in the recent war had attracted more attention and had received greater publicity than the less spectacular but no less important work of their medical colleagues. Statistics showed that in all great wars, and the recent war was no exception, more men were disabled as the result of medical conditions than surgical, and that disease was a more potent factor in the production of casualties than shell and rifle fire. The medical experiences of officers in France differed greatly and varied within wide limits according to the type of work they were called upon to perform. As the medical cases were for the most part transportable, and very properly were rapidly evacuated to the rear, the best place to obtain an accurate idea of the scope and importance of internal medicine in the A. E. F. was at a base hospital; particularly at a base hospital located in a rear area. Here they were allowed to remain for a sufficiently long time for careful diagnosis and treatment. The data used for the present report was taken from the records of Base Hospital No. 20 and covered the period of that organization's active operations in France. To this hospital a total of 8,706 patients were admitted. Of these 3,775 were surgical cases and 3,752 were credited to the medical section, leaving 1,179 to be divided among such special services as the genitourinary, eye, nose and throat. These figures did not differ essentially from those obtainable from the records of many of our overseas base hospitals as indicating the numerical equality that existed between the medical and surgical services. There were certain striking differences between the medical work seen in the hospitals of the A. E. F. and that encountered in civilian practice. In civil life the internist was called upon to manage diseases of all types, classes, and ages of people, whereas in the military hospitals of France his patients were drawn from a selected group of able-bodied, reasonably healthy young adult males, engaged in an exceedingly hazardous occupation and subjected to unusual degrees of exposure and fatigue in conjunction with bad living conditions, and frequently poorly prepared and monotonous diet. The result was that the medical patients in the military hospitals were for the most part suffering from acute conditions, such as acute affections, fatigue phenomena, and acute gastrointestinal disturbances. The medical cases met with in a base hospital could be divided into two main classes: (1) Those cases whose conditions was directly the result of the activities of warfare. (2) Those who were suffering from diseases not peculiar to war but which might overtake any individual at any time. The most conspicuous group belonging to the first class were those suffering from the effects of various deleterious poisonous gases, 1,415 such cases having been admitted to Base Hospital No. 20. In their experience, comparatively few of the gassed cases proved fatal, although many were seriously ill. This was not surprising in view of the fact that during the acute stage cases of gas poisoning were not transportable. The disabling manifestations of mustard gas poisoning were often delayed in their appearance and better opportunity of observing these cases was afforded than from any other type of gas poisoning. These cases were almost invariably suffering from external burns, for the most part limited to the genitalia, the buttocks, and parts of the body that were particularly moist from sweat. In many instances these burns were deep and severe, slow to heal, and decidedly disabling. In addition to these external manifestations, most of the mustard gas cases suffered from inflammation of the various mucous membranes. Inflammatory conditions of the respiratory tract varied from a slight laryngitis to a severe and wide-spread bronchopneumonia, and a certain proportion of cases had gastrointestinal symptoms, notably epigastric pain, intractable vomiting, and often persistent diarrhea. Of the 1,415 patients suffering from gas in one form or another, 1,375 were returned to duty, and only three died. This was conclusive evidence that the type of cases was not that seen near the front. Another group of cases that might properly be classed as battle casualties were those suffering from psychoneuroses and exhaustion. Few of these cases reached the rear area owing to the well organized work of Col. Salmon which provided for their care near the front. Of the 90 functional nervous cases that they handled in Base Hospital No. 20, 83 were returned to duty and only seven had to be transferred to neurological hospitals or returned to the United States. Of the so-called cases of effort syndrome, only 54 were admitted that could be regarded as effort syndrome *per se*. The method of handling these cases was that of graduated exercise so successfully carried out at Hamstead, England. Trench fever and trench nephritis were two other conditions that might be regarded as the direct result of war activities. In Base Hospital No. 20 trench fever was a rarity, only five cases of this infection having been observed. The freedom of the American troops from trench fever was worthy of note, inasmuch as in the British and French armies trench fever proved a serious cause of disability. One authority suggested that this was because the Americans were billeted in areas where infected lice were found in small numbers and where the number of trench fever carriers was so small as to prevent a general infection of the lice. The acute and subacute cases of nephritis in almost every instance followed some definite etiologic factor, such as a recognized acute infection. They differed in no way from nephritis as ordinarily observed, and could not be regarded as instances of trench nephritis. Among the cases belonging to Class 2, those suffering from diseases not peculiar to warmth by far the largest number suffered from influenza. Affections of the upper respiratory tract came next. Acute conditions of the gastrointestinal tract made up the next largest group, while tuberculosis, acute articular rheumatism, and pneumonia of various types were also of fairly common occurrence. In base hospital No. 20 influenza never attained serious proportions, only 598 cases of this infection being observed. It was believed that, in part at least, this was due to the early and careful precautions that were taken. All cases were immediately isolated and cubicilized. Doctors, nurses, and all attendants were required to wear caps, gowns, and masks whenever they entered wards in which influenza cases were being treated. After leaving the wards, it was made obligatory on them to thoroughly wash and disinfect their hands. Another factor that undoubtedly helped greatly in preventing the spread of the disease was that medical cases were housed in former hotel buildings so that instead of having a large number of patients in a single ward, the patients were divided into small groups quartered in separate rooms. They had treated 59 cases of pneumonia with 7 deaths. Only 5 cases of typhoid and 2 of paratyphoid were observed. Interesting observations were also made on cases returned as tuberculous.

(*To be continued*)

Surgical Effacement of Wrinkles.—Passot reports 42 successes from the practice of incision of the hairy scalp, the results of operation being subsequently concealed by the hair. The technique is not given but is presumably that of the so-called "tuck" taken in the smooth skin by cosmetic surgeons.—*Le Progrès Médical.*

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, October 8, 1919.

THE PRESIDENT, DR. B. FRANKLIN STAHL, IN THE CHAIR.

Deformities of the Spine and Joints.—Dr. J. TORRANCE RUGH of Philadelphia presented this paper, the purpose of which was to draw attention to certain fundamental facts regarding some of the common conditions which might be of practical value to the general practitioner. The ordinary spinal conditions he said might be grouped into: (1) the inflammatory or organic; (2) the noninflammatory or functional. These two classes were said to have in common the three symptoms of inflammation, pain, and deformity, and were not, therefore, usually differentiated by the medical man. The common impression among medical men that scoliosis was related, or due to tuberculosis, was said to be unfounded, the cause for such confusion being failure of the examiner to strip the patient and carefully examine the spine. The lower part of the back was said to present more variations from the normal than any other portion of the body, but that conditions such as subluxations were not shown by the *x*-ray. It was to be remembered that a slight deviation from the normal might in a given individual be a normal condition. In all cases of painful back the particular part affected was to be determined, the cause ascertained, and the appropriate treatment instituted. The old diagnosis of "lumbago," like that of "rheumatism," because of increased knowledge of etiologic factors, was termed obsolete. In chronic joint conditions tuberculosis was to be ruled out. This in the majority of cases was easily done. Other chronic joint affections had some distinguishing group of symptoms. In the treatment of inflammatory joint conditions the keynote was said to be rest. In cases of injury the possibility of trauma upon the joint or its structures, or whether the effect was a secondary one was to be considered. The importance of the latter influence Dr. Rugh thought not sufficiently recognized. The most important message the author thought he probably could bring was that joint cases should not be termed rheumatic until every other condition had been eliminated.

The Foot and Shoe Problem.—Dr. WALTER G. ELMER of Philadelphia referred to the foot as a well constructed mechanism, capable of an immense amount of work if properly treated, and easily giving way to strain if badly treated. The inner side of the foot—the longitudinal arch—was designated the weak side; the outer border, resting on the ground, the strong side. Thus was created the transverse arch. In correct walking it was said that the feet should be held parallel to each other and that the weight should fall chiefly on the outer side. Under faulty weight-bearing, the foot yielded gradually to strain, there was the overhanging inner ankle, the inner aspect of the foot became convex, and the anterior portion of the foot became abducted on the posterior part. Pain was attributed to abnormal strain on ligaments, bone pressure where it did not belong, and pressure upon or injury of nerve filaments between bones. Regarding footwear Dr. Elmer stated that an outline tracing should be made of the patient's foot with the weight upon the foot; the shoe should have a straight inner margin, a medium rounded toe, a square heel about 1 inch high for a man, 1½ inch high for a woman; the shoe should be as wide as the foot across the ball, and for the adult ¾ inch longer than the foot, and ½ inch longer for the child. In cases of foot strain it was advised that the inner margin of the sole and heel should be raised 3/16 inch. In more advanced cases a steel shank was to be put into the shank of the shoe, and a pad of firm piano felt fastened in the shoe to support the hollow of the foot. In cases of metatarsalgia this pad should be extended forward to support the metatarsal arch also, the support being just behind the heads of the second, third, and fourth metatarsal bones, a little higher behind the third. The ball of the great toe and the ball of the little toe should rest upon the sole of the shoe. Massage and flat foot exercises were also advocated. Pain might be relieved by baking in the superheated oven every other day.

Deformities of the Hand.—Dr. A. BRUCE GILL of Philadelphia outlined the various forms of congenital and acquired deformities of the hand, with their etiology, especial attention being drawn to Volkmann's contracture, and malunion of Colles' fracture. Volkmann's contracture, it was said, might be a very serious condition, partially or wholly destroying the use of the hand and disabling the patient for life. It was said to result from interference with the blood supply which was occasioned by fracture at the elbow, and less commonly, by fracture of the bones of the forearm. With proper reduction of the fracture at the elbow and appropriate application of the bandage circulation of the forearm and hand was not interfered with. If, however, attempt were made to dress the elbow in acute flexion without first reducing the fracture, pressure was made on the vessels in the flexure of the elbow, resulting in more or less complete obstruction of the circulation. It was emphasized that the arm should never be dressed in acute flexion until the fracture had been first reduced. Malunion of Colles' fracture was referred to as of extremely common occurrence. Many patients had passed months and even years with serious disability of the hand, the result of Colles' fracture, the disability often interfering with the patient's vocation. Here, too, the loss of function resulted from interference with the blood supply. The hand which became swollen and shiny was later blue and cold, and the fingers became more or less rigid, and treatment by baking, massage and manipulation failed, even through many months to secure return of function. Here, too, the condition of arthritis, with formation of fibrous tissue at the joints, was the result of interference with the blood supply. Many times it was impossible to secure complete flexion of the fingers even with the patient under an anesthetic. Proper reduction of the fracture precluded interference with the blood supply. Reduction should always be attempted under an anesthetic. In Dr. Gill's opinion, if a week after the fracture the hand and fingers were still swollen and motion were limited, with no evidence of rapid subsidence of the swelling, an open operation should be resorted to in order to secure reduction.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK.

New York, May, 1919.

(*Continued from page 908.*)

DIAGNOSIS.

1. How would you localize the site of (*a*) an injury to the spinal cord, (*b*) a tumor of the spinal cord?

2. Describe the effects of rachitis on the bones of the head, of the thorax, and of the extremities.

3. Differentiate between paretic ileus and mechanical obstruction of the small intestine.

4. Distinguish between syphilitic gumma of the liver and hepatic carcinoma.

5. Compare scurvy with beriberi; enumerate the distinctive symptoms of each and give their relative etiology.

6. Distinguish between the convulsions of epilepsy and those due to hysteria.

7. What are the symptoms produced by chilblains and on what do they depend?

8. State the symptoms indicative of cerebral abscess secondary to otitis media or mastoiditis.

9. Differentiate hydrothorax, pneumothorax, and pyothorax.

10. Differentiate between the bloody mucous discharges of dysentery and those caused by intussusception.

11. What is the diagnostic import of indican in the urine?

12. How may the distinction be made between absence of urine in the urinary bladder due to failure to secrete it and absence due to an obstruction of the ureter that prevents the urine from reaching the bladder?

PATHOLOGY.

1. Describe the pathology of acute osteomyelitis.
2. What pathological changes may take place in the liver in typhoid fever?
3. Describe the processes in the system occurring from shock.
4. Describe obliterating endarteritis.
5. Describe the pathology of a third degree burn.
6. Give the blood changes in Addison's disease.

BACTERIOLOGY.

7. How would you detect the cholera vibrios in cholera carriers and how would you use an immune serum to separate them from other vibrios?
8. How would you test a culture of tubercle bacilli to determine whether the bacilli were of a bovine or a human type?
9. Describe the Schick test.
10. Discuss the significance of bacilli of the colon group in drinking water when they occur in (a) small numbers, (*b*) large numbers.
11. Describe the Negri bodies. How would you test a dog's brain for rabies?
12. In the treatment of pneumonia by serum is it necessary to determine the type of pneumococcus? Give reasons for your answer.

ANSWERS.

DIAGNOSIS.

1. INJURY TO THE SPINAL CORD.—"*A total transverse lesion* gives rise to: (1) Complete flaccid paralysis of all the muscles innervated by the cord below the segmental level of the lesion; (2) complete anesthesia below the segmental level of the lesion; (3) absent knee-jerks and other deep reflexes below the segmental level of the lesion (occasionally the Babinski sign may be preserved); (4) atrophy of the paralyzed muscles; (5) partial or complete reactions of degeneration; and (6) loss of control over the vesical and rectal sphincters." *Lesions limited to one lateral half of the spinal cord* give rise to: "(1) On the side of the lesion: (*a*) motor paralysis on a level with and below the lesion—flaccid paralysis and atrophy, with the reactions of degeneration, of the muscles innervated by the segment of cord destroyed, and spastic paralysis of the muscles innervated by lower motor neurons below the destroyed segment of the cord; (*b*) a segmental zone of complete anesthesia corresponding to the spinal cord segment destroyed; and (*c*) below the level of the lesion—normal or increased protopathic and epicritic sensibility, but usually lessening of the deep sensibility (muscle sense). (2) On the side opposite the lesion: (*a*) lessened protopathic (pain) and epicritic (tactile and temperature) sensibility; and (*b*) normal deep sensibility, muscular power, and reflexes."—(Kelly's *Practice of Medicine.*)

Tumors of the spinal cord give symptoms of a unilateral lesion, motor paralysis on the side of and below the segmental level of the tumor, and anesthesia on the other side. If the tumor is large enough, it may give symptoms of a complete transverse lesion of the cord.

2. In *rachitis*, the *bones of the head* are thin and soft, the skull seems larger than usual, the fontanelles remain open for a longer period than is customary, and the forehead is prominent and large; the head is square. The *bones of the thorax* show a nodular enlargement at the junction of the ribs with the costal cartilages; the thorax is keel-shaped; there is a groove along the costochondral junction, and also along the attachment of the diaphragm. The *bones of the extremities:* The lower ends of the radius, ulna, and tibia are enlarged and deformed; bow-legs and knock-kees are frequent.

3. In *paretic ileus, the characteristic symptoms* are: "Absent peristalsis; progressive, uniformly distributed abdominal tympany, marked by a tense, rounded belly wall, in which individual intestinal coils cannot be felt; shallow, hurried respiration, because of upward pressure; rapid, weak, irregular heart action, caused at first by pressure, later by toxemia; profuse, persistently recurring, regurgitant vomiting of an offensive thin fluid, made brown or black by the presence of minute coagula; absolute constipation to both feces and flatus; and pain which, aside from that of the causative factor, is not severe, is not colicky in character, and is much bettered by the evacuation of gas."—(Martin's *Surgical Diagnosis.*)

In *mechanical obstruction of the small intestine* (in the absence of strangulation) there are: Gradual onset, preceded by constipation which though obstinate is not inveterate, and which often alternates with diarrhea; when the blockage becomes complete, distention and hyperperistalsis are both marked, and vomiting is recurrent and the constipation absolute. In case of strangulation there are: Sudden, violent, agonizing abdominal pain, usually associated with shock, immediate nausea, and vomiting, the latter persistently recurring, and a temporary diminution or complete cessation of peristalsis (reflex).—(From Martin's *Surgical Diagnosis.*)

4.

SYPHILIS OF LIVER.	CANCER OF LIVER.
History of heredity or of infection.	Of heredity or of primary growth.
Occurs congenitally; or, if acquired, at any age.	Never congenital; usually occurs after the age of forty.
Often accompanied by symptoms of tertiary syphilis — alopecia, rupia, etc.	Often preceded by the primary growth — pylorus, uterus, mammary gland.
Jaundice and ascites are common, especially the latter. No cachexia.	Jaundice and ascites rare. Marked cachexia.
The margin is markedly irregular, and neither nodular nor umbilicated.	Often the margin reveals the presence of umbilicated nodules.
Recovery may follow, or the affection may last for years.	Always fatal. Duration usually from a few months to a year.
Wassermann usually positive.	Rarely so.

—(Anders' *Practice of Medicine.*)

5. *Scurvy.*—"The onset is insidious, the early symptoms consisting usually of general ill health, weakness, anemia, and loss of flesh. The hemorrhagic manifestations usually begin in the gums, which become soft, swollen, spongy, hemorrhagic, and perhaps ulcerated; the teeth may fall out; the breath is very offensive, and the adjacent lymph nodes become swollen. Petechiæ and ecchymoses develop in and beneath the skin, especially of the legs; larger hemorrhages may develop in and between the muscles, especially of the calves, thighs, buttocks, abdominal wall, shoulder, etc., or beneath the periosteum, especially of the femur. Epistaxis, gastrointestinal hemorrhage, hematuria, and other mucous membrane bleedings, and serous membrane hemorrhages (especially into the larger joints) may occur. The hemorrhagic effusions, as a rule, become absorbed, but may break down into foul ulcerations. There may be erythematous, urticarial, and other skin eruptions. Cardiovascular and pulmonary symptoms of anemia (dyspnea, palpitation of the heart, edema, etc.); headache, mental depression and apathy, or delirium, etc., may supervene."—(Kelly's *Practice of Medicine.*)

Beriberi. The *rudimentary form* begins usually with pain and weakness in the extremities, associated with paresthesia and anesthesia of the leg. Slight edema also may develop, the muscles become tender, and palpitation of the heart, dyspnea, and abdominal uneasiness may be observed. The *paralytic* or *atrophic form* presents, as a rule, symptoms similar to the foregoing, but the pains in the limbs are more pronounced, and the muscles of the legs soon become paralyzed and atrophic. The paralyses and atrophy may extend to the muscles of the trunk, less frequently to the arms, head, and neck. The paralyses are usually flaccid, reactions of degeneration are present, and the tendon reflexes are absent. The areas of anesthesia and of paresthesia are often irregularly distributed. The cardiac symptoms are not pronounced, and the edema is usually slight. The *dropsical form* begins as the preceding forms, but edema soon appears, and the patient, as a rule, speedily becomes anasarcous. Palpitation of the heart, rapid heart action, dyspnea, and cyanosis of the extremities are quite marked. Paralyses and muscular

atrophy are not as pronounced as in the other cases. The urine is diminished in amount, but, as a rule, contains no albumin."—(Kelly's *Practice of Medicine.*)

Scurvy is due to lack of organic acids such as are found in fresh vegetables and fruit, and to excess of salt meat and fish.

Beriberi has been said to be due to bacteria, to protozoa, to various chemical causes, to deficiency of nitrogen in the food, to deficiency of vitamines in the food, to intestinal parasites, to the use of polished rice as a food. The nitrogen, lack of vitamines, and polished rice theories are the ones most generally accepted.

6.

CONVULSIONS OF EPILEPSY.	CONVULSIONS OF HYSTERIA.
Usually previous attacks or slight seizures.	Hysterical and dyspeptic symptoms.
Affects either sex; often hereditary; no apparent exciting cause.	Affects females, as a rule; usually mental excitement or bodily fatigue.
Invasion sudden; scream, distortion of face, and pallor.	Often gradual; palpitation, choking, or other hysterical symptoms.
Loss of consciousness sudden and complete.	Often gradual and incomplete.
Biting of tongue usual.	Absent.
Involuntary micturition usual.	Absent.
Talking and screaming absent.	Often present.
Duration of attack rarely more than ten minutes.	Often prolonged.
Attack followed by deep sleep; sometimes delirium.	Exhaustion; no tendency to sleep or delirium.

—(From Fenwick's *Medical Diagnosis.*)

7. A *chilblain* is an inflammatory hyperemia, usually involving the fingers, toes, or ears, and determined by exposure to cold. It is generally seen in young people with defective circulation. After the period of anemia and pallor the part begins to itch or burn, and becomes red, swollen and shiny. Exudation occurs into and beneath the skin, and in bad cases a blister with bloodstained contents forms; when this bursts troublesome ulceration ensues.

8. *Cerebral abscess secondary to otitis media.* "The *symptoms* in traumatic cases are acute, and as there is usually diffuse meningitis, there is intense pain, fever, and rigors, coma quickly supervening. In the more common chronic cases the symptoms are often vague in the early stages, but when well marked consist in signs of intracranial pressure. 1. The *headache* and tenderness are severe, and localized to the site of the abscess. 2. The *temperature* is subnormal, unless there is associated meningitis. 3. The *pulse* is markedly slowed, even down to 30 or 40. 4. The patient is quite intelligent, but *cerebration* is very slow; vomiting and optic neuritis are usually present. 5. *Motor symptoms* may occur if the abscess is in the anterior part of the temporo-sphenoidal lobe, either irritative or paralytic. If the cerebellum is affected, there is giddiness both while walking and lying down, together with weakness of the hand grip and increase in the knee jerk on the side affected. Lateral nystagmus often occurs."—(*Aids to Surgery.*)

9. HYDROTHORAX.—*Inspection* shows immobility of the chest walls, with some enlargement on the affected side; the intercostal spaces may bulge, and there is displacement of the heart beat. *Palpation* shows the vocal fremitus to be absent. *Percussion* shows flatness or dullness, with increased resistance to the pleximeter finger. *Auscultation* shows absence of respiratory sounds except at the upper part of the compressed lung, where bronchial respiration and bronchophony or egophony are heard. *Aspiration* shows a serous fluid.

PNEUMOTHORAX.—*Inspection* shows immobility on the affected side; the intercostal spaces may bulge; the heart is displaced to the sound side. *Percussion* gives a tympanitic note, sometimes the note is high pitched and dull, but never flat (as it may be in hydrothorax). *Palpation* shows absence of tactile fremitus. *Auscultation* shows voice and breath sounds enfeebled or absent; a metallic tinkling sound may be detected on speaking or coughing; amphoric breathing may be heard.

PYOTHORAX.—High and irregular fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis. Absolute diagnosis is made by aspiration, showing the fluid to be pus.

10. The bloody mucous discharges of *dysentery* should contain either the *amœba hystolytica* or one of the bacilli causing the disease. In the case of *intussusception* no such organism would be present (though the *amœba coli* might be found).

11. *Indican* (in excess) is found in the urine in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation; or when there are excessive putrefactive changes occurring in the intestine; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc.—(From Witthaus' *Essentials of Chemistry.*)

12. In case of *obstruction of the ureter*, the passage of a ureteral catheter will determine the presence and site of the obstruction; and if this obstruction can be passed by the catheter, there will be a prompt flow of urine. When *no urine is secreted* the above procedure is negative in results.

PATHOLOGY.

1. *Pathology of acute osteomyelitis:* "The marrow first becomes red and edematous, then cellular infiltration and proliferation are superadded, and finally collections of pus or diffuse purulent transformation follow. The surrounding bone is involved, becoming more or less infiltrated, softening, and not rarely undergoing necrosis. Small or large sequestra may be formed, or the bone may necrose completely. Periostitis is generally associated, and the tissues around the bone are usually infiltrated and suffer suppurative or necrotic changes. Hypertrophic changes may occur in the periosteum and superficial layers of bone, causing a bony encasement of central sequestra. In such instances a suppurating sinus, extending from the bone to the surface, usually remains."—(Stengel's *Pathology*)

2. *The liver in typhoid fever:* "The liver early in the disease is usually hyperemic, firm and somewhat enlarged, but later it becomes paler and more friable. The structure of the lobules is usually not so evident on section. The most marked change is a parenchymatous degeneration, which may vary much in different parts. The liver cells at first are granular, turbid, and show fatty change, while after this they may contain granules and drops of fat and later on disintegrate. This process begins most commonly at the periphery of the lobule and is usually more marked here than at the center. There may also be nodular areas, probably of two kinds, one being considered as lymphoid nodules, while the others are apparently necrotic. Mallory considers that there are two varieties of these lesions; in one there are phagocytic cells in the lymph spaces and around the portal vessels; the second is due to the obstruction of the capillaries by phagocytic cells which have been carried by the portal circulation from their point of origin from the endothelium of the vessels of the intestine and spleen. Following this the liver cells lying between the capillaries undergo necrosis. These lesions are not peculiar to typhoid fever."—(Osler and McCrae's *Modern Medicine.*)

3. "The explanation of shock usually accepted, largely on the authority of Crile and Mummery, is that the paralysis or exhaustion of the vasomotor center in the medulla results in a lessening of the vascular tone, particularly that of the arteries, and a marked fall in the blood pressure. Most of the blood leaves the arteries and collects in the large venous trunks, especially those of the abdomen, and there is thus produced an anemia of the brain and of the superficial parts of the body. At the same time the right side of the heart becomes overloaded and impeded in its action. According to J. D. Malcolm the disturbance of the vasomotor center results, not in dilatation, but in contraction of the arteries. At first the superficial vessels are constricted, and if the exciting cause is kept up this condition spreads back to the larger vessels, so that the blood is

driven out into the tissues and back into the abdominal veins."—(Thomson and Miles' *Surgery.*)

4. *Obliterating endarteritis.* This is a condition in which the internal coat of an artery becomes very markedly thickened, and ultimately either obliterates the lumen of the vessel or leads to thrombosis. There is no tendency to degeneration of the newly-formed tissue. It occurs in various diseases, especially in syphilis, where the smaller arteries are affected, in the brain, and around gummata. It occurs also in diabetics and alcoholics, and then larger arteries, like the posterior tibial, are affected, leading to defective nutrition of the limb, and even gangrene. In the neighborhood of tubercles there is always a condition of chronic obliterative arteritis.

5. *Pathology of a third degree burn:* "In the *third degree* the cuticle is destroyed, as is also part of the cutis vera, but the tips of the interpapillary processes, including the exquisitely sensitive nerve terminals, are laid bare and left intact; consequently this is a most painful form of burn. The deeper structures of the skin—viz., the sweat and sebaceous glands, and the hair follicles—remain untouched, so that, although the surface during the healing process becomes covered with granulations, the integument is very rapidly replaced, since there are so many epithelial elements from which it can grow. The cuticle is able to form not from the edge only, as must occur wherever the whole of the cutaneous envelope is destroyed, but also from innumerable foci scattered over the wound surface. The resulting scar, though often white and visible, undergoes no contraction: it is supple and elastic from containing all the elements of the true skin."—(Rose and Carless' *Surgery.*)

6. *The blood changes in Addison's disease:* In mild cases and in the early stages the number of red cells is normal; in severe and advanced cases there is a marked diminution in the number of red cells. Nucleated red cells are very rarely seen. The hemoglobin approximately follows the anemia. The leucocytes are generally about normal in quantity, but there may be a moderate increase in eosinophiles and in lymphocytes. Cases have been reported where there was a leucocytosis, and also where there was a leucopenia.

BACTERIOLOGY.

7. *Cholera vibrios in cholera carriers are detected* by examining the feces. "The most satisfactory method of procedure is to inoculate a set of gelatin plates, another of agar plates, and a number of Dunham's pepton-broth tubes, with small quantities of the suspicious material. When the spirilla are numerous they can frequently be fished directly from suspicious colonies in the plates and isolated for further identification. When less numerous, they can usually be found in relatively increased numbers after eight or ten hours at 37.5° C., in the topmost layers of the Dunham broth, which is an almost selectively favorable medium for these organisms. They collect at the surface where free oxygen is readily obtained. From the pepton broth plate dilutions can then be prepared and colonies fished. Once isolated, the spirilla are identified by their morphology, by the appearance of their colonies, by their manner of growth upon gelatin stabs, by the cholera-red reaction, and, finally, by agglutinative and bacteriolytic tests in immune sera. Owing to the existence of other spirilla morphologically and culturally similar, the serum reactions are the only absolutely positive differential criteria."—(Hiss and Zinsser's *Bacteriology*)

To separate them from other vibrios by the use of an immune serum: "Make two hanging-drop preparations, using mucus from the stool as the bacillary emulsion. To one add an equal amount of a 1:50 normal serum; to the other a 1:500 dilution of immune serum. Cholera spirilla remain motile in the control, but lose motility and become agglutinated in the preparation with the immune serum."—(Stitt's *Practical Bacteriology*, etc.)

8. *To differentiate human and bovine types of tubercle bacilli:* "The bovine type grows slowly on serum and at the end of two or three weeks shows only a thin grayish, uniform growth which is not wrinkled and not pigmented. The human type grows more rapidly and tends to become wrinkled and pigmented. Subcutaneous inoculation of 50 mg. of culture into the neck of calves produced generalized tuberculosis. A similar injection of human T.B. does not cause generalized tuberculosis but only an encapsulated local lesion. Intravenous injection of 0.01 to 0.1 mg. of bovine T.B. into rabbits causes general miliary tuberculosis and death within five weeks. With human T.B. in doses of 0.1 to 1.0 mg., similarly injected, the majority of rabbits lived for three months. Subcutaneous injection of 10 mg. bovine T.B. causes death in 28 to 101 days. Similar injection of human T.B. in doses up to 100 mg. did not kill the rabbits after periods of from 94 to 725 days. The duration of life in injected guinea-pigs is longer with human than with bovine T.B."—(Stitt's *Practical Bacteriology*, etc.)

9. *The Schick reaction:* "The test is performed as follows: With a small sharp hypodermic needle we inject intradermally $\frac{1}{50}$ of a minimum lethal dose (1 M.L.D.) of diphtheria toxin as determined for a 250-gram guinea-pig. The standardized toxin is so diluted with a ½ per cent. carbolic acid solution that 0.1 c.c. contains $\frac{1}{50}$ of a M.L.D. A positive reaction shows within twenty-four hours, reaching its maximum intensity in two days, as a reddened area, about one inch in diameter with more or less induration. The reaction persists for about a week, leaving a brownish pigmentation. Positive reactions show that the patient has less than $\frac{1}{30}$ of a unit of antitoxin in 1 c.c. of his blood serum and that he possesses no immunity to diphtheria."—(Stitt's *Practical Bacteriology*, etc.)

10. *Significance of bacilli of the colon group in drinking water:* Rosenau states that a ground water should be condemned even if only a few colon bacilli are found, for, as he puts it, "these bacteria have no business in a soil-filtered and properly protected well or spring-water. Surface waters, however, may easily contain a few colon bacilli without necessarily having been exposed to contamination by human feces. The limit of safety, Rosenau states, is one colon bacillus per c.c. If more are present the water should be regarded as suspicious. If more than 10 per c.c. are found the water must be regarded as dangerous and unqualifiedly condemned."—(Hiss and Zinsser's *Bacteriology*)

11. The *Negri bodies* are peculiar structures found in the cells of the central nervous system of rabid dogs. They are chiefly found in the Purkinje cells of the cerebellum and in the large cells of the hippocampus major. It has been suggested that these bodies are of protozoan origin, also that they are degeneration products. They are round or oval, and measure from 5 to 25 micra in diameter.

To test a dog's brain for rabies: A small pin-head sized piece of brain tissue from the hippocampus major or cerebellum (containing Purkinje cells) is placed on one end of a slide under a cover glass and the cover is gently squeezed with the finger until the tissue is flattened out into a thin layer. The glass cover is then gently shifted across the slide until the brain tissue is smeared along the entire surface. These smears may be fixed in methyl alcohol and stained by the Giemsa method. Stained in this way, the Negri bodies are stained light blue, in contrast to the darker and more violet cell-bodies. The presence of these bodies is indicative of rabies.—(From Hiss and Zinsser's *Bacteriology*)

12. In the serum treatment of pneumonia it is absolutely necessary to determine the type of pneumococcus; because, while there are four recognized types of pneumococcus, an efficient serum has only been prepared against type I organisms and not for those belonging to the other groups. This serum has no beneficial effect on the other types.

(To be continued.)

Leprosy in the Netherlands in the Middle Ages.—Our knowledge of the details of medieval leprous incidence is far from complete as documents collected by antiquarians frequently come to light. In *Janus* for May-June, 1919, van Andel gives a very circumstantial account of the disease in the low countries in which it did not become extinct until the middle of the XVII century. The author has searched through the archives of several small towns for data, whence it appears that until about 1516 the lepers mingled without restraint among the healthy population. This state of affairs apparently led to a renewed dissemination of the disease and the people made application to have the lepers interned. But diagnosis of the disease was not always easy and many people were classed provisionally as suspects under observation. These were sent to certain centers for expert examination and were required to be reexamined every four years. Until certified as free from disease they were treated as actual lepers and had to sojourn at the leproseries of the villages through which they passed, although apparently, unlike the known lepers, they could inhabit their own homes. Once pronounced a leper one could thenceforth sojourn and dwell only in leproseries. Documents show abundantly that these rules were in full force at the close of the XVI century (the leprosery at Leyden dated from the year 1444).

At a later period, during the XVII century, these laws were probably relaxed, for leprous tramps and beggars seem to have been familiar figures in the low countries. There were of course plenty of fake lepers in apparently good health who were willing to pose as ill for the sake of the revenue from begging. The lepers depicted in contemporary art seem to have been crippled, with atrophic limbs, shrivelled face, depressed nose, etc. This facies was regarded as characteristic. Mutilated limbs suggested gangrene of the extremities. Nodular or tubercular leprosy is not depicted in art. The fish theory, later advocated by Hutchinson, was held by many, but while the Englishman believed in the causation of the disease through the consumption of badly cured fish, the physicians of the period accused fresh fish as well and at one time the consumption of fish and milk together was accused pointedly. Such views did not interfere with the belief in contagion. During the middle ages the term ladrerie was synonymous with leprosy but eventually came to acquire a different significance in connection with affections due to sensible parasites and transmitted from animals to man.

Felix Plater.—This practitioner of Basle was born in 1536, received his medical degree at the age of 21 and practised medicine in his native city for half a century where he was also a University professor. He was physician to several princes and founded a botanical garden. Of interest is the fact that lemon trees grew in the latter without forcing. This fact suggests that the climate of Switzerland at that time must have been warmer than it is at present.—*Revue médicale de la Suisse romande.*

THEORY AND PRACTICE OF PROTEAL THERAPY.

BY HENRY SMITH WILLIAMS, M.D.,

NEW YORK

IN a previous article, a condensed summary was given of the clinical records of 100 patients recently treated by me with nonspecific vegetable proteins—for which I have suggested the generic name Proteals.

Reference to this list will show that the pathological conditions involved cover a wide range. The list includes intestinal toxemia, anemias, endocrine disturbances including exophthalmic goitre, tuberculosis, neurasthenia, psoriasis, asthma, cancer, leukemia, arthritis, albuminuria, glycosuria, duodenal ulcer, arteriosclerosis, melancholia, dementia præcox, epilepsy, pharyngolaryngitis with aphonia, probably of specific origin, aortic aneurysm, brachial neuritis, lenticular paralysis, eczema, psoriasis, and an indolent ulcer of the tibial region, apparently neither tuberculous nor malignant.

With regard to all of these conditions, with possibly one or two exceptions, it was explicitly suggested that tangible benefits, at least of palliative character, had apparently resulted from proteal medication.

At first blush, the suggestion that any single therapeutic principle may have application throughout so wide a range of maladies or pathological conditions, seems absurd. Fully cognizant of this, I have always taken pains, in addressing medical gatherings on the subject of proteal therapy (as I have done on more than a hundred occasions within the past two years) to point out at the outset, at the risk of boring my auditors with technical deails of physiological chemistry, the essential nature of the protein response in therapeutics; calling attention at the same time to the fact that there is a fundamental point of contact (namely, disturbance of protein metabolism) between a wide range and variety of maladies of middle life and old age having the most divergent symptomatology.

When this is done, the suggestion that proteal therapy may have application as a palliative, and in many cases even as a curative, agency throughout even such a wide range of maladies as that just listed no longer seems absurd. On the contrary, there is sound apriori foundation for the assumption; and it may not be without interest to recall that the prediction that protein therapy would be found applicable to a very wide range of maladies was made by me at the time when I first put forward the thesis of the protein response, in the *New York Medical Journal* of October 2, 1915.

Basing my arguments on the tenets of the proteomorphic theory I postulated nonspecific proteins as antigens to be directed against all forms of disturbance of metabolism involving protein infection. Although practical experience at the time concerned only a single group of maladies, I confidently predicted the application of the method throughout a far wider field. Believing that a disturbance of protein metabolism underlies practically all the so-called degenerative maladies of maturity and old age, I could see no reason why the field of nonspecific protein therapy should not be coextensive. I predicted that the nonspecific protein method "must in future rank with serum therapy and vaccine therapy—if, indeed, it does not altogether outstrip or totally supplant both these relatively new additions to the equipment of the practical physician."

It will hardly be disputed, I think, that the developments of the four intervening years have served to give an extraordinary measure of support to this prediction. During that time an ever-increasing body of evidence for the validity of the proteomorphic theory and its therapeutic application in the nonspecific protein response has accumulated. So far as I am aware, no other comprehensive theory of the action of nonspecific proteins has been presented. My published studies of blood modifications under proteal treatment serve at least to give the theory a considerable measure ot verisimilitude. Meantime clinical experience has extended to an ever-widening range of maladies, in my own personal experience and in the experience of several hundred associated physicians. My recent observations, as summarized in the table of cases presented in the former article, typify the experience of scores of other physicians who have used proteals from my laboratory in their private or hospital practice, and have thus cooperated with me in determining the applications and limitations of the new method. Fragments of evidence from this comprehensive experience will be presented as we proceed. Full presentation must await another occasion, since even to epitomize the available records would carry us far beyond present spacial limits.

I emphasize the personal character of this experience, because the nonspecific protein therapy here in question—the antigens employed being non-toxic vegetable proteins—is something quite different from what has been described as nonspecific protein therapy in a number of articles in recent periodical literature, in which the antigen was the specific typhoid-bacillus vaccine. Where the latter agent

is employed, it is obvious that we introduce specific bacterial toxins along with the protein, and the alleged "typical protein reaction" evoked, characterized by severe chill and moderate cyanosis lasting from fifteen to twenty minutes and followed by a period of profuse sweating and marked elevation of temperature, and usually by pronounced leucocytosis, is something quite different from the response evoked by non-bacterial vegetable proteins, particularly when these proteins are partially hydrolyzed as in the case of proteals prepared in my laboratory.

With these partially hydrolyzed vegetable proteins—reduced to the stage of metalbumin, proteose, and peptone—administered in the dosage which I employ and recommend, there is no such "typical protein reaction," as that just described. The patient comes to my office for treatment, and immediately thereafter goes about his or her business, manifesting neither objective nor subjective symptoms beyond a negligible tenderness at the area of the hypodermic injection, and, in some cases, a mild sense of exhilaration. The anaphylactic symptoms above mentioned may, indeed, be produced when the unbroken protein molecule is employed, and were described in my earlier writings on the subject as constituting a reaction to be expected; but the nonspecific vegetable proteins prepared in my laboratory during the past two and a half years and used exclusively in my practice during that period are free from this defect.

It is, indeed, one of their greatest practical therapeutic merits that, in the words of a recent commentator, these proteals produce action without reaction.

It is obvious that otherwise the proteals would not be practically applicable to a large proportion of the cases listed in the table above presented. Neurasthenic women, cases of moderate intestinal toxemia, "general debility," anemia, and mild endocrine disturbance obviously could not be expected to submit to a prolonged course of proteal treatment were any such disagreeable reaction involved as that above described as characteristic of "the protein response."

In a word, then, the bacterial vaccines, used nonspecifically, whatever their merits in the heroic treatment of arthritis and of acute infections (for example, pneumonia) have a relatively limited range of application. It is an open question whether such use of toxic specific vaccines (something quite apart from their recognized function of immunization) is ever justifiable when truly nonspecific and relatively nontoxic proteins are available, capable of producing a true "protein response" without the complicating and unwelcome feature of anaphylaxis.

The Nature of the Protein Response.—We have already noted in general terms the character of this nonspecific protein response. It is desirable, however, to examine it somewhat more in detail because a clear understanding of it is essential, as above suggested, to adequate comprehension of the therapeutic possibilities of this method of medication.

Let me emphasize at the outset that there is nothing mysterious about this protein response, except in the sense that all physiological reactions are in the last analysis mysterious. If the thesis of the proteomorphic theory—to the effect that the blood corpuscles are the agents engaged in decompounding all foreign proteins that enter the blood stream—is valid, then there is nothing more mysterious about the protein response in therapeutics, as I conceive it, than in the fact that gastric juice is secreted when protein foods are taken into the stomach.

The proteins in the stomach evoke a response from the cells of the gastric mucosa resulting in the secretion of enzyme-bearing gastric juice.

The foreign proteins in the blood stream evoke a reaction from the cytogenic (hematopoetic) mechanism resulting in the extrusion into the blood stream of enzyme-bearing corpuscles.

In each case we have the stimulus of direct contact, and the physiological response is as primitive and fundamental in character in one case as in the other. No physiological function is simpler, more directly responsive, or less involved in mystery. The response to a bacterial antigen, in which the cells of the organism—here again, as I believe, the corpuscles being largely involved—produce a specific antitoxin, is another illustration of the same type of direct, primordial reaction.

It is not too much, then, to say that we have a tangible or visualized knowledge of the mode of action of the specific vaccines and nonspecific proteins that does not attach to the older and more familiar therapeutic agencies. No one knows how or why the effects of morphine, atropine, or digitalis are produced. We cannot form even the vaguest mental picture of the method of action of these drugs.

But we can form a very clear mental picture of the anatomical and physiological changes that take place when a moderate quantity of nonspecific protein—that is to say a nonbacterial protein—is injected into the subcutaneous tissue, and absorbed into the blood stream.

We can in imagination picture the molecules of the foreign proteins coming in contact with corpuscles in the bone marrow and spleen and lymph nodes.

Accepting for the sake of argument the tenets of the proteomorphic theory, we can picture the mononuclear leucocytes and in particular the large monocytes, as being stimulated to give out enzymes of tryptic character, capable of beginning the proteolysis of the proteins, just as the cells of gastric mucosa and pancreas do under analogous circumstances. We can picture the red corpuscles as stimulated by contact with intruding protein by-products of peptone or polypeptid order to give out enzymes capable of continuing the hydrolysis of these substances; just as the enteric mucosa gives out similar enzymes to complete the hydrolysis of the end-products of ordinary protein digestion.

Incidentally, we may note that the corspuscles are doubtless called upon to exercise their auxiliary digestive functions pretty constantly on partially decompounding products that escape the activities of the digestive enzymes and find their way through the intestinal wall without having been reduced to the amino-acid state—such intrusion constituting, in my opinion, the essential characteristic of intestinal toxemia.

Following up this line of thought, we are confronted by the inference that intestinal toxemia, as

here defined, is in itself a form of protein medication, calculated to stimulate the corpuscles and blood-forming mechanism. Such, doubtless, is the fact. The familiar post-prandial leucocytosis, largely lymphocytic in character, probably represents nature's method of safeguarding the organism against the intrusion of unbroken proteins. A mild degree of insufficiency of the intestinal wall is doubtless adequately compensated by the normal equipment of corpuscles, white and red; indeed, what we term normality in this equipment is presumably the balance that nature has struck in the long process of evolution to represent the average needs of the average organism.

It is only when these average needs are exceeded, as in the case of an individual who eats excessive quantities of protein foods, or whose digestive apparatus functionates feebly, that a protein invasion overtaxes the capacities of the normal corpusclar supply; the intestinal toxemia then becoming a measurable factor in the economy of the organism, characterized at first by increased activity of the cytogenic mechanism (erythrocytosis, leucocytosis), and subsequently by exhaustion evidenced by anemia and by sundry groups of ancillary symptoms affecting ultimately every organ in the body, this one or that more prominently according to the hereditary susceptibilities of the individual.

It is suggested in the text that intestinal toxemia constitutes in effect a protein-product invasion of the blood stream. Bearing this view in mind, it is not surprising to find the blood count approximately normal, or even supranormal, in many cases of intestinal toxemia as yet uncomplicated by tangible sequential involvement of distant organs or tissues. The exceptions are cases in which the prolonged over stimulation of the cytogenic mechanism has led to exhaustion, with resultant anemia. Note the fresh response to the new proteins in Cases 2437 and 2461, and the average response throughout. Averages are of course somewhat deceptive where the number of cases involved is so small; they are complicated, for example, by such cases as 2391, 2440 and 2441. Nevertheless, the general result—increase of hemoglobin and red corpuscles and decrease or normalization of the leucocytes—is typical of the protein response as revealed by thousands of observations. It will be seen that other tables of the present series are corroborative.

In all this, however, we are getting somewhat ahead of our story. Let us return to the hypothetical increment of parenteral protein (perhaps introduced hypodermically) which we have visualized as engaging the attention of the white and red blood corpuscles. Let us recall that these corpuscles, in pursuance of their functions, must elaborate enzymes comparable to the enzymes of the familiar digestive fluids. It has been experimentally proved that they are capable of producing such enzymes. But of course a cell cannot produce enzymes or other synthetic products without exhausting its energies and its corporeal substance. Such exhaustion in the case of the corpuscles is probably accompanied by actual destruction of the cell itself. The familiar fact of prompt disappearance of the post-prandial leucocytes a few hours after digestion is completed, and the equally familiar destruction of something like three per cent of all the red corpuscles daily in the spleen and liver, justify this assumption.

It appears, however, that such destruction of the corpuscles in itself liberates agents that act as hormones stimulating the cytogenic apparatus to produce corpuscles to supply the gaps in the ranks. In the original presentation of the proteomorphic theory (1914), I suggested that the enteric hormone secretin, which is known to stimulate the activities of the pancreas, stimulates the cytogenic apparatus also to the production of the post-prandial galaxies of leucocytes. The suggestion has been validated by the experiments of recent physiological workers (Macleod and Pearce).

If the digestive cells of the intestinal walls produce such a signal-bearing hormone, the red corpuscles in exercising their auxiliary digestive function may very well put forth a similar messenger. But in addition to this, the molecules of invading protein in the blood stream will, as a matter of course, be brought more or less in contact with the cells of the blood-forming mechanism; and, as already suggested, they may directly stimulate these cells, just as other protein molecules in the stomach stimulate the cells of the gastric mucosa.

The net result is that shortly after the introduction of a foreign protein into the blood stream, there is tangible evidence of a definite response of the cytogenic apparatus. If the proteins are bacterial (for example antityphoid vaccine) the response has the character of a leucocytosis with a preponderance of polynuclears, these being preeminently the fighters of bacteria, as the investigations of Metchnikoff showed many years ago.

If, on the other hand, the protein invasion consists of molecules of animal or vegetable origin (alfalfa seed protein, for example), the response is evidenced in a mild leucocytosis (or even in a reduction of the count, if hitherto excessive), with pronounced monocytosis, and in particular with relatively great increase of the large monocytes, these being the cells that chiefly begin the decompounding of nonbacterial proteins.

A monocytosis is, as I have previously suggested, as characteristic of a nonbacterial protein invasion as a polyneucleosis is of a bacterial invasion.

It may further be noted that if the nonbacterial invaders include the unbroken protein molecules, the galaxies of eosinophiles will also be increased. The monocytosis and the eosinophilia of protozoal infection are thus at least provisionally explicable.

Meantime there will take place a corresponding modification of the cohorts of red corpuscles. Too much stress should not be laid on the mere numerical count of the corpuscles. It must be recalled that the value of the erythrocytic cohort depends not merely upon the numbers, but upon enzymic activities. Not infrequently in practice we find a polycythemia when there is reason to believe that the

These are cases of inoperable cancer selected primarily because of their clinical interest. All of them showed remarkable progress at the time when the later counts were made In several cases this progress resulted in clinical recovery; others are still under observation.

The chief interest of the present table lies in the light it throws on modifications of the differential leucocyte count under Proteal treatment, as gauged in connection with the time element. It will be seen that, after this particular group of patients had been under treatment for an average of 55 days, the large monocyte count might be said to be in a static phase, inasmuch as it represented only 12.9 per cent of the total leucocyte count, which is substantially the percentage noted as the typical average of untreated cancer cases. Yet four months later (on the average) these patients showed such an active response to the continued Proteal treatment that their average large monocyte count was 24.8, not far from double the count of the earlier period. The total mononuclear count had risen from 29.9 to 40.5.

The practical physician will think it not altogether unimportant that the observed microscopical changes harmonize with records of the clinical progress of the cases of inoperable cancer under consideration.

enzymic functions of the corpuscle mass as a whole are performed inadequately. This condition obtains in many cases of hyperthyroidism. The numerical excess of red corpuscles with deficiency of enzyme or hormone production is, I believe, strictly comparable to the proliferation of cells of the thyroid gland in the same individual, with resultant tangible goitre, superinduced by an original defect in the hormone-synthesizing or iodine-conserving qualities of the thyroid cells. More detailed reference will be made to this aspect of the matter in a moment.

While the differential count of leucocytes is thus modified in characteristic fashion as a part of the protein response and the red corpuscles are normalized in number and in enzymic activities, it is notable that such normalization includes the hemoglobin content no less than the proteolizing enzymes. I have records of many scores of cases in which the percentage of hemoglobin has advanced rapidly under proteal treatment, without other medication; suggesting, it may incidentally be noted, that even in cases of extreme anemia there is usually an abundance of iron available in the ordinary diet, or perhaps in the liver, to meet all corpuscular needs, awaiting only enhanced capacity of the corpuscles to utilize it in the synthesis of hemoglobin.

It seems impossible to doubt the direct evidence of the microscope that such enhanced capacity to synthesize hemoglobin takes place under stimulus of nonspecific protein injections; and it is obvious that oxidation of the by-products of catabolism must thereby be facilitated. Blood thus normalized through gain in numerical count of corpuscles and enzyme-generating capacity must exercise a beneficent influence on the organism at large. Reaching every cell in the body, and being the sole purveyor of oxygen and the chief purveyor of food pabulum and the all-essential enzymes lacking which the vital processes would stagnate, the normalized blood must influence the individual activities of every cell and the aggregate activities of the collections of cells called vital organs.

These cases, selected solely with reference to the numerical status of erythrocytes before treatment, include cases listed in other tables. No case is omitted, within the limits of the series under consideration, in which the original count showed less than 4,000,000 red corpuscles. The object in bringing these cases together is to illustrate the tendency of proteal treatment to normalize blood conditions regardless of the pathological antecedents of the secondary anemia. In this table further analysis of the red-corpuscle count after treatment shows these averages: For the 6 males, 5,144,666; for the 16 females, 4,645,000.

For example, since synthesis of digestive fluids—gastric, pancreatic, enteric—must result from material sent through the blood stream, it is almost axiomatic to say that the quantity and quality of these digestive fluids are subject to the influence of abnormal blood conditions. Anemic blood may prevent the formation of adequate digestive fluids; with resultant defective digestion, which in turn will impoverish the blood, thus creating a vicious circle.

But if we cut into this vicious circle with the hypodermic needle, introducing nonspecific proteins of a type with which the organism is not familiar and to which it will therefore respond with peculiar energy, we stimulate the cytogenic apparatus to new activity, increase the number of corpuscles, enhance the material for better gastric fluid, leading to improved digestion and a better supply of pabulum to feed the corpuscles. We thus establish a wholesome circle. And when one has accomplished this over and over, with various cases, one ceases to doubt that the hypodermic needle was the implement that inaugurated this feat of jugglery.

Theory Tested by Practice.—Such, then, are the essential features of the nonspecific protein response as I conceive it. I have urged that such blood changes as those just noted might be postulated from the knowledge of the proteomorphic theory. But it must be clearly pnderstood that I did not formulate the original interpretation of the protein response, much less the present reiteration of it, on any such mere theoretical basis. The proteomorphic theory did serve at the outset as a guide. It enabled me, for example, to postulate as a protein response the therapeutic results attained with extracts of conglomerate character in which protein was one of several constituents. But I did this only tentatively until I could prove through my own experimental and practical investigations with pure vegetable protein that the response was due entirely to this agent.

Whereas the blood responses might have been postulated from the proteomorphic theory, they were in point of fact posited as the results of a synthetic study involving the microscopical examination of thousands of blood specimens.

The modifications of the blood response to the injections of nonspecific proteins (nonbacterial) are matters of observation—independent of any theoretical explanation. That these observed facts coincide with and support a physiological theory ascribing new functions to the blood corpuscles and materially extending our conception of the processes of metabolism, is a matter assuredly not lacking in interest, yet one with which the practical user of nonspecific proteins does not of necessity concern himself.

In my own office, every case of whatever character is subjected to blood examination. But whoever wishes may administer the proteals by rule of thumb, and guided by clinical manifestations alone, may be assured of results in a great variety of cases showing varied manifestations of disturbed metabolism that will gratify the patient and redound to the credit of the practitioner. There are scores of practitioners scattered about the country, some of them in cities and some of them in villages, to whom I have sent proteal ampules—often by the gross—regularly during the past two years, who have no time to use the microscope, and who take pathological findings on trust, but who have become enthusiastic over the clinical results of proteal therapy falling under their observations as physicians. The major part of these men are experienced and skilful practitioners, and their evidence is of a character that no candid man would ignore.

Table IV.—Table Grouping the 13 Unselected Cases Introduced in the "Proteal Clinic," but not Included in the Consecutive Series of 100 Cases; Introduced for the Sake of Completeness.

Average numerical increase							14,918	923
Percentage of increase						12.1	0.3	14.3

A group of cases so small as this, where the units are so diversified, has little statistical value. The group includes two cases that were not under observation until some time after proteal treatment had been instituted. The majority of the remaining cases chance to be of types characterized by high count of red corpuscles. The percentage of modification was therefore small (just as, contrariwise, it was excessive in the group of anemic cases); nevertheless, the final figures show the average blood conditions normalized with results in many ways similar to those shown in the other groups. Further analysis of the red-corpuscle count after treatment shows the following averages: For the 6 males, 4,919,666; for the 5 f males, 4,963,600. The anomalous balance (females higher than males—found in no other table of the series) is in part accounted for by the exceptionally low count of Case No. 2489. It may be noted, that all these are relatively recent cases, in which the normalizing influence of the proteals has not yet reached the maximum. Compare with other tables.

But there are also physicians among my corroborators and correspondents who, thanks to hospital associations or private laboratory facilities, are able to follow the blood modifications of patients under proteal treatment as they are followed in my own office and laboratory. Numbers of these physicians—some of whom I have never seen—have confirmed my observations as to blood modifications under proteal treatment, in individual cases, or in large groups of cases. In at least one instance the pathologist of a sanatorium extended the observations beyond the point of my published records, noting that the blood of several proteal-treated tuberculous patients showed a modification of the polynuclear leucocytes in the way of shift of the Arneth index to the right—a modification which, it will be recalled, is considered significant of favorable progress.

On another occasion I shall present in detail the evidence, clinical and pathological, as to the applications and limitations of proteal therapy made available by reports of these scores of independent workers. But as the informal reports already in hand aggregate the bulk of a good sized volume, I shall not attempt to summarize them here. Suffice it for the moment that, whereas several hundred physicians have used the proteals from my laboratory, not one has sent me a report expressing scep-

ticism as to the therapeutic value of proteal therapy. As a matter of course, physicians have failed to get results in individual cases; but without exception in reporting such negative results, expressions have been added of interest in the method and desire to test it in other cases.

Meantime a vast majority of the reports tell of interesting modifications, palliative or curative, directly ascribed to the proteal medication. The aggregate experience is such as to give one a confidence in the method that could hardly be attained through individual observations, however extensive. It has seldom happened, I presume, that an individual worker has been able to accumulate so large a body of evidence for the value of a new therapeutic procedure in so short a time.

The Question of Specificity.—Reverting now to the table of personal cases above presented, I wish to review briefly various groups of maladies or pathological conditions summarized with regard to the available experience as to the value of proteal therapy, and in particular to suggest the rationale of remedial action in the light of the hematological features of the protein response.

To avoid endless repetition, let me say once for all that I make no suggestion of "specific" action in the application of proteals to any of the maladies in question. To talk of specific nonspecific proteins is obviously a contradiction of terms—althongh a specific protein may of course be used nonspecifically.

Table V.—Blood Conditions in a Consecutive Series of Cases of Neurasthenia Under Proteal Treatment.

As suggested in the text, the diagnosis of a case as "neurasthenia" is not a very satisfactory one. Nevertheless the cases grouped together under this heading represent a fairly well defined clinical syndrome. As to blood conditions, there is a characteristic condition of anemia, modified or complicated by the character of the endocrine disturbance and of the intestinal toxemia almost always more or less in evidence. The average results in this table show characteristic increase of hemoglobin and red corpuscles; whereas the white corpuscles remain unmodified in the general average, which is consonant with theory, noting that the average before treatment is within the bounds of the normal. It will be observed, however, that the individual cases that originally departed widely from the normal in either direction (for example, 2401, 2425, 2447, and 2448) show the characteristic tendency to normalization. Further analysis of the red-corpuscle count after treatment shows the following averages: For the 8 males, 4,964,000; for the 8 females, 4,614,000.

There is, however, no incongruity in the suggestion that proteals may ultimately be prepared that will act specifically—that is to say selectively—on various organs of the body. Investigations along the lines of such possible extension of proteal therapy are in progress. Discussion of this new aspect of the subject, however, scarcely falls within the scope of the present paper. We are here concerned with the direct response, that is a protein response per se—susceptible of explication, at least in general terms, as applying to all foreign proteins. It will be recalled that I have suggested the generic term "proteantigen" as a convenient name by which reference may be made to any protein-bearing preparation used as an antigen, either specific or nonspecific, including therefore vaccines, serums, and proteals, and also such nonspecific animal extracts as egg protein, milk protein, and various autolysates, for which I have suggested the generic name "proteils."

Our present concern is with the nonspecific proteantigens only, and in particular with the proteals, though much that will be said as to the general response applies to the proteils also.

I have pointed out that the direct response to the nonspecific proteantigens involves stimulus to the blood-forming mechanism, resulting in an increase of hemoglobin, normalization (usually increase) in the count of red corpuscles, and normalization (often decrease) and differential modification of the white corpuscles. The action is so direct that one might perhaps be justified in speaking of the proteals as "specific" remedies for anemia. But anemia itself is a condition rather than a malady—commonly associated with most of the degenerative conditions. It enters into the vicious circle in connection with cancer, rheumatism, tuberculosis, Bright's disease, diabetes, and the like. I have already suggested the way in which the introduction of nonspecific protein may modify the circle and tend to establish a wholesome circle in its stead. The application may be made, in a measure at least, to chronic maladies involving any organ of the body.

A moment's reflection shows the logic of application of protein therapy as at least an auxiliary treatment practically throughout the range of chronic maladies, inasmuch as there are no harmful results from the treatment.

I make this assertion as to harmlessness with a large measure of confidence, in particular with reference to the vegetable proteins. I have personally administered many thousands of doses of proteals and, as already noted, have sent out hundreds of thousands of doses to other physicians. I have yet to observe, or to have reported to me, harmful results of any character. The rare case of mild anaphylaxis which has no permanent ill effects is certainly no valid exception. Bedridden invalids, seemingly on the verge of moribundity, and frail children, have received the proteal treatment, and the effect uniformally observed is tonic rather than debilitating. So far as I have observed, there are no contraindications. Proteals may be administered in connection with any other line of medication.

I repeat, then, that according to this view proteals are indicated as probably desirable accessories at least, if not as the chief therapeutic agent, in the treatment of practically every type of malady involving disturbed metabolism or nutrition. Such disturbances furnish the point of contact between

all the different maladies of middle life and old age—the acute infections being somewhat doubtfully excepted. An adequate supply of normal blood is never a disadvantage to any organ, and the proteals preeminently tend to aid toward securing such a supply.

Stated in clinical terms, proteals stimulate nutrition. I am of the opinion that they have more universal applicability than any other therapeutic agent available.

It would be easy to fortify this personal opinion by citing at length the observations of collaborating physicians by the score. I content myself with a single brief quotation from a letter that chances to come to hand just as this article is being revised for publication, to this effect:

"I am using the proteals in any and every variety of run-down conditions, and have not scored what I consider a failure yet. Particularly I wish to note their wonderful results in middle and old age conditions where lack of life and energy from any cause seems to exist. Uniformly the report seems to be: 'They make me feel 10 or 15 years younger'."

This statement, be it noted, comes from a middle-aged practitioner of high standing and wide experience, to whom I have sent, first and last, not far from 200 dozen ampules of proteals (about 6,000 average doses), and who had previously reported with like enthusiasm results attained in the proteal treatment of postsyphilitic conditions, hypertension, goitre, tuberculosis, and psoriasis.

Proteal Treatment of Wasting Maladies.—The application of this capacity of the proteals to modify the blood in such a way as to improve disturbed metabolism or stimulate nutrition, to the varied group of "wasting" maladies—tuberculosis, Bright's disease, diabetes, cancer, pernicious anemia—is too obvious to call for extended comment. The practical results of such application in a large group of cancer patients, a fairly large group of tuberculous cases, and smaller groups of the other maladies have been gratifying. In many cases these results are of a more definite and tangible character than might perhaps have been anticipated. In cancer cases, for example, including postoperative recurrences and cases that have been *x*-rayed and radium treated, and which have turned to the proteals as a last resort, the effects of treatment are often for a time at least nothing less than startling.

I have published statistics of 766 such cases. A condensed summary of one group of 284 cases, of which 209 were carcinomas, 52 epitheliomas, and 17 sarcomas, 6 being unclassified, shows that where pain was present it was favorably modified by proteal treatment in 77.4 per cent of cases; offensive discharge, where present, was favorably modified in 85 per cent; and the general health of the patient was favorably modified in 70 per cent; and the condition of the neoplasm itself was favorably modified in 60 per cent of cases, there being marked regression in size in a brief period in 26.8 per cent.

I have explained these results as due to the modified corpuscular conditions; in particular to the great increase of large monocytes (advancing sometimes from the normal of four or five per cent to 15, 20, 25, and even 35 per cent of the total leucocytes), these being the agents most directly concerned with the initial hydrolysis of protein molecules, which in effect make up the cells of the malignant neoplasm; the action of the mononuclears being supplemented by the final hydrolytic activities of the red corpuscles, completing the decompounding of the aforetime cancer-cell molecule from the polypeptid stage.

THE BLOOD IN CANCER SUBJECTS UNDER PROTEAL TREATMENT.

Modification of the blood count following the administration of fairly vigorous Protea treatment. Particular attention is called to the notable increase in the large mononuclears. Such a modification is certainly one of the most characteristic, and perhaps the most important, of the changes brought about by the proteal treatment. Note also the increase in hemoglobin and in red corpuscles, and the decrease in white corpuscles as a whole and in the percentage of polynuclears.

These cases are grouped together imply because they are cases in which an original blood count, made before treatment, was supplemented by a subsequent count after treatment. They are otherwise quite unselected

Whatever the theoretical explanation, however, the observed effects are tangible, and the early progress of such cancer cases under proteal treatment is exceedingly gratifying to all concerned. It must be added, however, that in order that this

progress should be continued and be cumulative, it is necessary to increase the dosage of proteals rather rapidly, and from time to time change the type of protein.

The fact that a particular type of protein will not suffice to make the blood modifications permanent in cases where there is serious infection, as in cancer, was established by my observations three years ago, and reported in detail in the Monograph of December, 1916. It remains to add that I am still searching for and working with new proteins to supplement those already in hand. At the present stage of development, the proteal treatment of malignant cases is palliative and not curative. Most cases hitherto treated were beyond hope of anything but palliation. Nevertheless a few cases appear to have been carried to a stage of arrested development that justifies a hopeful prognosis. It is reasonable to expect that the proportion of such cases will increase very markedly when proteal treatment is administered to large numbers of cancer cases at an earlier stage. New and hitherto untried proteins (including many from sources genetically far afield) will be utilized from time to time; and it may reasonably be expected that more effective proteins, vegetable or animal, than those hitherto used will ultimately be available; or new series that can evoke successive responses the cumulative effect of which will be observed in the final elimination of the neoplasm, provided treatment is inaugurated at a reasonably early stage.

Let me urge, however, that in the ultimate view the true solution of the much bruited cancer problem is to be found not in dealing with established cancer itself, but in treatment of precancerous conditions. According to the commonly accepted estimate, one woman in eight and one man in eleven, beyond the age of 35, dies ultimately of cancer. This means that in every series of 100 noncancerous cases coming before you, there are 12 or 9, according to sex, that will subsequently develop cancer—unless your treatment tends to ward off such development. The possible benefits, in this connection, of the normalizing of metabolic conditions with the aid of proteals, must be obvious. I shall deal more at length with the subject, presenting an analysis of the hematological evidence, in another connection.

Meantime there are one or two comments that I may perhaps advantageously introduce by way of summary from the Monograph published almost two years ago, and reiterated in my book last year.

"One of the greatest merits of the proteal treatment is that it enables isolated physicians, in the remotest hamlets, to do something tangible and definite toward ameliorating the condition of the cancer patient who has passed beyond the reach of the surgeon.

"Thanks to the new treatment, the most inexperienced practitioner can do more to-day for the amelioration of the condition of a late stage, inoperable cancer case than could hitherto be accomplished by the most experienced practitioner in the best metropolitan cancer hospital."

I trust that I shall not be thought oblivious of the truth that evolution is necessarily slow if I point out, quite without rancor, that these conclusions and the elaborate statistical data upon which they are based were published by me in a prominent medical journal more than four years ago; and that in the intervening period at least a quarter of a million victims of cancer in the United States alone have gone on their long journey unsolaced by proteal treatment. Thousands have desired the treatment and have been denied its benefactions, although the proteals have been at all times freely available—for rich and poor alike.

Since the publication of my Monograph on cancer, at least ten thousand victims of cancer have died within local telephone call of my office and laboratory, and all but a half dozen of these have been denied the benefactions of the proteal treatment which I would only too gladly have made available for them with the cooperation of their physicians.

Such a situation, could we view it retrospectively across the vista of two or three centuries, would doubtless seem grotesquely humorous. "Quaint old bigots, those antediluvian ancestors of ours," we would say with a laugh. But viewed from the contemporary standpoint, there is an element of pathos that tends to obscure the humor of this type of conservatism. Doubtless it will make small difference in the ultimate scheme of cosmic events whether these mortals died early or late, or whether they suffered much or not at all; but to the individuals themselves, here and now, it seems to matter more than a little. And the humane physician is supposed to sympathize with the contemporary viewpoint.

Table VII.—Blood Conditions in a Consecutive Series of Tubercular Cases Under Proteal Treatment.

Percentage of increase.....						13	7.5	− 18.4

Note the hyperleucocytosis characterizing a bacterial infection, and the tendency toward normalization of the leucocyte count under proteal treatment. The red corpuscle count is frequently high in tuberculosis, as the table suggests. Reduction of erythrocytosis may coincide with favorable progress, as in Case 2458. More important than mere numerical change, however, is the modification of enzymic properties, often suggested by the altered appearance and modified osmotic properties of the cells. Further analysis of the red-corpuscle count after treatment shows the following averages: For the 6 males, 5,459,333; for the 9 females, 4,956,444.

The Application in Tuberculosis.—But let us not quarrel with the laws that govern human progress. Let us turn to more heartening aspects of proteal treatment. Consider, for example, the relatively rapid extension of the method as applied to tuberculosis. From a single institution where, only six months ago, they grudgingly undertook the treat-

ment experimentally, I received a few days ago a request for a supply of proteals to treat fifty cases for three months. Sundry smaller institutions and numerous individual physicians are treating tuberculous cases, and reports of a very gratifying character have come to me, to supplement the records of my personal experience.

It must be understood, of course, that no suggestion is made that proteals will "cure" tuberculosis. The word "cure" is one that the wise physician uses very sparingly—or eschews altogether. It is not posited even that proteals offer treatment having any specific effect on the tubercle bacillus. What is suggested is that the proteals, thanks to their capacity to stimulate favorable blood modifications tending to improve general metabolism, may be instrumental in fortifying the system against the invasion of the tubercle bacillus or enhancing the organic powers of resistance so that the organism can overcome the invader. In other words, the proteals furnish an important agent in increasing the oxidation and improving nutrition—well recognized desiderata in the treatment of the malady.

I believe that the proteals have further value in developing great cohorts of large monocytes that may be instrumental in breaking down the neoplasmic growths associated with secondary infection, to which rather than to primary tuberculous invasion the patient usually succumbs. There is also the probability of increased resistance through stimulus to enzymic activities.

I have already said that the profession has responded with relative alacrity to the suggestion that proteals be used extensively for institution cases. The number of cases of tuberculosis hitherto treated runs well into the hundreds. Statistical data as to results are not yet available, but many gratifying reports of individual cases are in hand, supplementing my personal experience. A very extensive application of proteal therapy in this field in the immediate future may be expected.

Possible Immunizing Value of Proteals.—As a matter of course the question was often asked last winter during the influenza epidemic as to what might be expected of proteal treatment in relation to the malady. My answer was that the question of the proteal treatment of acute infections must for the time being be held entirely in abeyance, awaiting evidence. I ventured to express a hope, however, that patients under proteal treatment might show an exceptional degree of resistance to the invasion of the influenza virus.

There is a certain amount of evidence to suggest that this hope was justified. Of the group of proteal patients undergoing treatment in my office during the incidence of the epidemic, numbering more than one hundred cases, only two individuals developed symptoms of influenza, and in one of these the attack was so mild as to make the diagnosis doubtful. Moreover, I received reports from several physicians in various parts of the country, including one from a Texas physician in a region where the epidemic involved an exceptionally high percentage of the population, in which the opinion was expressed that proteal patients appeared to be more or less immune to influenza. It will, of course, be necessary to secure a very much wider body of evidence before any definite conclusion in the matter can be arrived at. I hope that tests may be made on an extensive scale, and under conditions that permit unequivocal conclusions to be arrived at during the ensuing winter should the influenza again become epidemic, as is not impossible.

It has been reported that patients suffering from influenza tend to show modifications of blood characterized by a reduction of white corpuscles and a relative increase of eosinophiles and mononuclears. If these modifications are characteristic such changes suggest that the virus of influenza is not bacterial but protozoal, constituting, therefore, a different type of protein toxemia from that directly induced by the germs of the bacterial order. Under these conditions, it might be theoretically expected that the proteals would stimulate a leucocytic and erythrocytic response of a character calculated to combat the invasion. On this assumption, the immunizing value of the proteals should be greater than that of bacterial vaccines; and active proteal treatment after the incidence of the malady might also be indicated.

All this, of course, involves the assumption that a protozoal germ is in question. It is by no means certain, however, that immunizing value might not attach to the nonspecific proteantigen even if the influenza germ is bacterial. For it must be recalled that it involves no contraindication to assume that the enhanced production of specific enzymes may well fall within the scope of the general corpuscular response to the nonspecific proteantigens. This possibility was explicitly suggested in my first theoretical interpretation of the protein response (October, 1915): and the idea has found practical support in the recent seemingly successful use of nonspecific proteins in the treatment of influenzal pneumonia as reported by Roberts and Cary and by Cowie and Beaven in the *Journal of the American Medical Association* of March 29 and April 19, 1919, respectively. Roberts and C[illegible]te Herrmann (*J. Infect. Dis.*, November [illegible]cluding that "the intravenous injec[illegible]n tein serves as a stimulus for the lib[illegible] antibodies in animals in which t[illegible] injected [specific?] antigen was unable such a liberation"; and they add: "In other [illegible] while the therapeutic injection is nonspecific, t[illegible] antibody response is specific."

Moreover, the conception of nonspecific protein therapy implied in "the possibility of seeking for collateral immunization by inoculating a microbe or mixture of microbes other than that with which the patient is infected" now has the high authorization of Sir Almroth E. Wright himself, as expressly stated in his lecture before the Royal Society of Medicine, Feb. 25, 1919.

I make this citation from among sundry other available ones of similar tenor, to show that the view as to the comprehensive character of the protein response which I put forward in 1915 and elaborated the following year, is no longer regarded as hopelessly heretical. Nevertheless, I offer the above suggestions as to the probable immunizing value of the proteals with much diffidence; the more so as it is my present purpose to deal with the past accomplishments of proteal therapy and not the theoretical possibilities. I wish to add also that

one very accomplished clinician has reported negative results from the use of the proteals in pneumonia (although commending highly their value as aids to nutrition in chronic conditions, including tuberculosis). On the other hand another competent clinician at an army camp reports that in his experience the proteals proved superior to any vaccine or serum in pneumonia cases. Obviously the question as to the possible value of nonspecific proteins in acute infections must await further evidence.

Possibly it may be of interest, as further illustrating the relatively wide experience with the proteals of physicians with whose cooperation I have been favored, to note that the two clinicians just mentioned (they are in nowise associated, one residing in the East and the other on the Pacific Slope) have between them received from my laboratory more than 300 dozen ampules of proteals for use in private and hospital practice. The experience of these two physicians alone, therefore, covers the administration of perhaps 10,000 doses of proteals; the patients treated, in addition to private cases and military-camp cases, being distributed among five important city hospitals, and the maladies involved including notably asthma, cancer, goitre, and tuberculosis.

The Proteal Treatment of Hyperthyroidism.—Reverting to the table of cases, it will appear that a frequently recurring condition is that of hyperthyroidism. The cases in question range from a mild type of thyroid disturbance to conspicuous exophthalmic goitre. The practical results in a high percentage of cases have been very gratifying. The results attained, coupled with the importance of the subject, make it perhaps desirable to refer to these cases somewhat more at length.

Here we appear at once to be confronted by a paradox. An important effect of proteal therapy, as we have seen, is to produce blood conditions tending to normalize metabolism or improve nutrition. But the patient suffering from hyperthyroidism is the victim apparently of overactive metabolism. He (or more commonly she) rather characteristically shows supernormal blood conditions—hemoglobin 100 per cent. or more; red corpuscles perhaps five and a half million; white corpuscles frequently numbering ten thousand. Familiar calorimetric studies have shown that basal metabolism is increased—oxidation of tissues taking place with more than normal rapidity. The patient may eat well, may digest food well, and yet lose weight. The heart runs like a trip-hammer, and the patient is under nervous tension and presents sundry neuropathic symptoms associated with the general condition of overexcitation. Disturbed cutaneous circulation reveals marked aberration of the vasomotor system. Meantime there may or may not be a tangibly enlarged thyroid gland giving a clue to the true mediate cause of the varied disturbances.

To casual observation, with such a syndrome as this, it might seem that proteal therapy is distinctly contraindicated. Yet several cases were presented in a previous article that seemed to give unequivocal evidence of the benefit derived from the proteal treatment. Indeed, the results cited in several cases were apparently so unequivocal as to be demonstrative. The list might have been notably extended but for limitations of the consecutive series; and I may add that records of a good many other cases are available, sent to me by physicians who have used the proteal treatment for goitre, that are directly confirmatory. It is true that in certain cases, where there is very marked toxicity, it may be desirable to supplement proteal therapy with the use of thyroid antitoxin, made after the manner of antitoxins in general, by inoculating a sheep with thyroid protein. This, however, has been done only exceptionally for a short period, in less than 10 per cent. of the cases under consideration. For the rest, proteal treatment alone, or associated with small doses of potassium iodide, appears to be responsible for the favorable progress of cases, some of which had long resisted other lines of treatment.

Table VIII.—Blood Conditions in a Consecutive Series of Cases of Dysthyroidism Under Proteal Treatment.

Most of the cases here presented were cases of hyperthyroidism; but every close student of endocrine disturbances knows how variable the functioning of the thyroid may be at certain stages of departure from the normal, and how generally hypofunction and hyperfunction as regards different elements of the thyroid secretion are associated. Rather characteristic hematological features of hyperthyroidism are relatively high hemoglobin index and red corpuscle count, with a leucocyte count that may be high or distinctly low; in the former case there being a characteristic lymphocytosis, contrasting with the polynucleosis of tuberculosis. In atypical cases hemoglobin and red corpuscles may be deficient. The normalizing effect of the proteals in this group of cases is fairly well brought out in the summary of averages, but the individual cases will repay examination. The average red-corpuscle count in this group after treatment is: For the 5 males, 5,049,600; for the 11 females, 4,947,300.

Under these circumstances, proteal treatment of hyperthyroidism would appear to be practically indicated, whether or not we can explain theoretically the beneficial action of the remedy. But there is alawys an added satisfaction in knowing the rationale of a therapeutic procedure; and when I state that in the present instance I was led to apply the proteal treatment to goitre on theoretical grounds, it will be evident on one hand that the action is explicable and on the other that my conception of the nature of hyperthyroidism is perhaps slightly different from the orthodox conception.

The readers of my book may recall that I have listed goitre among the so-called cancerous conditions. Possibly the phrase precancerous would be more logical. I do not mean to imply that an enlarged thyroid is really cancerous or malignant, although it is only too well known that there is a marked tendency to merge into malignancy. What

I do mean to imply is that the hyperplastic tissue of the goitre is more or less subject to hydrolysis through the action of normal enzymes of the blood stream. The amount of such hydrolysis may vary indefinitely. In some cases it is negligible, and the goitre does not add directly to the symptoms of protein-toxemia. In other cases it is conspicuous, and very marked toxicity results. The original development of the goitre was usually, or perhaps always, associated with a condition of protein toxemia, generally having its seat of origin in the intestinal tract. The additional increment of protein products in the blood from proteolysis of thyroid tissues tends to accentuate the disturbance that led to the development of the goitre; in other words, tends to facilitate further growth of the goitre itself.

But why should the presence of protein by-products in the blood stream (as from the intestinal toxemia) stimulate the thyroid gland to hyperplastic development in the first instance? Probably because the thyroid normally secretes enzymes that tend directly to neutralize certain of the toxins of protein origin, or hormones that stimulate the activities of the cytogenic mechanism, to the end that more corpuscles bearing these enzymes may be produced. In this connection the recent observation that the thyroid gland and the red corpuscle contain enzymes having similar properties is suggestive. The observation, just cited, that cases of hyperthyroidism commonly show a high count of erythrocytes is also corroborative of the idea just suggested that the thyroid hormone contains a cytogenic stimulant.

It remains to note, however, that the normal thyroid, in a subject having no pronounced hereditary tendency to goitre, may doubtless fluctuate as to its secretion in response to the varying presence of toxins, without undergoing hyperplastic development—that is to say, without the development of a goitre. The more or less heritable deficiencies, or tendencies to aberration of the thyroid, are probably somewhat varied in character. In one case we may have to do with the capacity to retain iodine and synthesize the organic iodine compound that appears to play so important a role in the functioning of the organism. In that event, the hyperplasia of the thyroid tissue may represent an attempt at compensation; but the attempt is disastrous (hypothyroidism merging into hyperthyroidism) because the large gland now secretes in excess the hormone that tends to control the vasomotor activities; and the balance between this hormone and the compensatory hormones of the posterior pituitary and the suprarenals is destroyed.

Hence the tachycardia, and general vasomotor disturbance, tending to accelerate cellular activities, as evidenced in increased basal metabolism; and the disturbed digestion and assimilation, as evidenced frequently by glycemia, and by lymphocytosis and polycythemia (to handle the excess proteins), merging variously into anemia and leucopenia through exhaustion of the cytogenic mechanism; and the fluctuating but characteristic rheumatoid symptoms, neuralgic pains, headache, backache, nausea, and disturbance of the menstrual function.

In such a case the utility of the administration of iodine at an early stage is obvious, and this by itself may go a long way toward restoring the hormone balance, by taking away the necessity for overaction of the thyroid in order to secure a sufficient quantity of iodine to meet the needs of the system. Meantime the proteals will tend to normalize the corpuscular conditions both as regards enzymic activities of all corpuscles and as regards the differential status of the leucocytes. By increasing the ranks of the large monocytes and the red corpuscles they may facilitate the handling of foreign proteins, including the excess of glandular tissue of the thyroid itself. If, now, additional attention is given to the digestive tract, in particular by the use of laxatives operating on the upper intestine (cascara, rhubarb and soda mixture, phenophthalien, bile salts, salines); and, secondly, if the diet is for a time restricted, with practical exclusion of the animal proteins, thus reducing the total protein intake—the condition of intestinal toxemia will be attacked from both sides, so to speak, and a favorable modification of the pathological conditions all along the line may be expected.

Proteal Therapy and Hypertension.—Limitations of space forbid that I should attempt an analysis of the conditions of disturbed protein metabolism associated with asthma, psoriasis, and arthritis. It must suffice to remark that the proteal treatment of these conditions is dealt with somewhat extensively in my book. Some interesting cases of arthritis are summarized in the table (Nos. 2406, 2407, 2432, etc.). The one case of asthma in the present list gave negative results; but I had previously reported cases of the most gratifying character, and the highly satisfactory results of a much extended experience are now available and will be elaborated in another connection.

I must not close, however, without making somewhat more extended mention of one other condition to which no reference has been made in my previous publications, but which has been the subject of fairly extensive observations in recent months—namely the condition of hypertension, or high blood pressure. My observations are not yet sufficiently extensive to permit a comprehensive generalization, but so far as they go they tend to suggest that proteal therapy may have a direct effect in lowering the blood pressure where hypertension is associated with a considerable variety of conditions of disturbed metabolism. It remains to inquire very briefly whether there is theoretical warrant for accepting these clinical observations consonant with known characteristics of the protein response.

In the simplest analysis, it is obvious that blood pressure depends upon three variable factors—force of heart beat, resiliency of the vascular walls, and relative fluidity of the blood. Changes in blood pressure may be brought about through operation of any one of these factors. The modification to which attention is most commonly directed is the change in the arterial walls constituting arteriosclerosis. Temporary changes are of course produced by modifications of the heart beat varying with exertion and by fluctuation in vasomotor control.

A less commonly considered source of variation of blood pressure concerns the fluctuating viscosity of the circulating medium itself. Frictional resis-

tance to the flow of the blood under uniform conditions of the vascular walls must vary markedly with changes in the number of corpuscles and their individual qualitative conditions. Under conditions of protein toxemia the blood cells, both red and white, often appear to have exceptional agglutinative quality, and where this is the case the blood pressure would naturally be increased unless there were some compensating modification of the heart power or arterial resistance. In point of fact, where the condition of protein intoxication obtains for a long period, there is a well-known tendency to modification of the arterial walls in the direction of rigidity—often complicated by endocrine disturbance; so the two causes often combine to increase the blood pressure. The heart beats more rapidly and with enhanced force for a time; and the familiar syndrome of hypertension is clinically evident.

Table IX.—Blood Pressure Under Proteal Treatment.

Case No	Name.	Diagnosis.	Before Treatment.		After Treatment.		Proteal Treatment.
			Systolic	Diastolic	Systolic	Diastolic

Percentage of decrease.....					17.8	12.3	

In another connection, a much wider series of cases showing modification of blood pressure under proteal treatment will be examined. This table, however, presents a group showing modifications that appear to be characteristic so far as present experience goes. As stated in the text, the present observations are regarded as only tentative but they are at least suggestive.

Under such conditions, the observed beneficial action of the proteals is exerted, we must suppose, primarily through modification of the blood. I have been unable to note any effect whatever of the proteals upon the heart, although I have administered large doses for protracted periods to persons manifesting a great variety of heart conditions. It is true that the tachycardia of hyperthyroidism is conspicuously modified under proteal treatment but this, I am confident, is an indirect effect, resulting from such modifications of the blood conditions as are under consideration in our discussion of the moment. These modifications consist essentially of normalization as regards the number of corpuscles and enzymic properties, with the removal of the abnormal accumulation of the partially hydrolyzed protein products in the blood plasm, with resultant lowering of the viscosity of the circulating fluid as a whole, thus directly tending to lower the blood pressure. The effect may presently be accentuated, probably by direct reaction of the capillary walls and almost certainly by indirect modification of vasomotor conditions due to the improved quality of the blood supply to the nerve centers.

Further modification may result, I believe, from changes in the arterial wall itself, in cases where the hyperplastic development of the cell (beginning arteriosclerosis) has occurred; neoplastic cells of this character being, I believe, more or less subject to modification through the changed corpuscular and enzymic conditions brought about by the proteals. But the primary modification in a great majority of cases is due in all probability to direct change in the blood conditions.

To what extent the proteals may be depended upon as palliative or curative agents in cases of hypertension in general, is a question that must await more extensive observations. But the records of the small series of cases (about 150) already in hand are at least suggestive of interesting possibilities in this direction.

The same remark may be applied to the allied and often directly associated conditions of disturbed metabolism presenting the clinical picture of diabetes and Bright's disease. It is superfluous to suggest the probability that a therapeutic agent which tends to normalize metabolism in general may be of service, at least as an auxiliary, in the treatment of conditions so directly evidencing metabolic disturbance. The number of cases hitherto treated is small, but with one exception they give very gratifying support to this presumption. It is to be expected that in the near future tests will be made on a large scale, and reports of more comprehensive character will presently be available.

Neuroses and Psychoses.—The same comment may be made regarding sundry neuroses and psychoses represented by individual cases in the table given in the first section of this article. We have but to recall that the nervous system is preeminently dependent upon a good blood supply for its normal functioning to gain a clear conception of the way in which proteal therapy may be of aid in rehabilitation of functional, and even structural, disturbance of the nervous mechanism. Moreover, the common association of these conditions with endocrine disturbances, and the tendency of the proteals to normalize endocrine action through modification of the hemotopoetic apparatus (itself, in my opinion, an important member of the endocrine system), must not be overlooked. It would be premature, however, to attempt to forecast the relative status of the proteals among recognized therapeutic agents in this field.

But for that matter, it would be premature to attempt to say anything final regarding the relative status of proteal therapy in other fields of therapeutics, even where the method has been used for a longer time and far more extensively. Suffice it that the evidence in hand not merely justifies but necessitates the conviction that in the nonspecific proteins—of which proteals furnish at the moment the most readily available example, and the one hitherto most extensively employed—the medical profession is provided with a valuable addition to the accepted therapeutic equipment. In the above pages I have necessarily presented only fragments of the available evidence in support of that view.

I trust, however, that enough has been said to arouse the interest of many physicians who hitherto have not tested the new method. When fifty thousand practitioners are regularly using the proteals, our knowledge as to the clinical applications and limitations of the method will go forward by leaps and bounds.

This conglomerate group of cases is introduced for the sake of completeness. In connection with the tables for intestinal toxemia, neurasthenia, tuberculosis, and dysthyroidism, it completes the series of 100 cases tabulated as to clinical conditions at the beginning of the previous article. Notwithstanding its conglomerate character this group of cases shows the characteristic features of the protein response as indicated by modifications of hemoglobin, red corpuscles, and leucocytes. After-treatment average of red corpuscles: For the 10 males, 5,237,200; for the 14 females, 4,772,857.

It is even more important, perhaps, that institutions having large groups of patients of one type or another—tuberculous, Bright's disease, diabetes, cancer, psychoneuroes—should test the method; for example, treating every other patient taken in the order of admission, so that half are treated and half serve as controls. I have suggested this method to the authorities of several institutions having from one hundred to two thousand patients, and I believe that such tests will be made in the near future.

Meantime the new fields of study already entered or planned for early investigation in my own office and laboratory include the following:

1. The testing of new types of proteins from various botanical fields, including the lower orders (Thallophytes, Bryophytes, Pteridophytes), and from germinating seeds; the original tests being made as heretofore, with guinea pigs. In view of the wide qualitative difference in antigenic response between bacterial proteins and seed proteins, it may reasonably be expected that responses of yet another order may be evoked by, for example, bryophytic proteins. Again, the question of possible selective actions of proteins from plants of recognized therapeutic value, directed toward specific organs (liver, kidneys, lungs, brain), to supplement the general cytogenic response, is at least worthy of investigation.

TABLE XI.—RECAPITULATION AND ANALYTICAL SUMMARY OF BLOOD CONDITIONS AS MODIFIED DURING PROTEAL TREATMENT IN THE 113 CONSECUTIVE CASES TABULATED AND DISCUSSED IN THIS ARTICLE.

Percentage of increase	...	...	....	...	13 00	28.4	6.5

There are no duplications in the first six groups here listed, the total being 113 cases—the 100 consecutive cases first tabulated, and the 13 additional cases that appeared at the "Proteal Clinic." The cases making up the final group were, it will be recalled, selected because of their anemic condition from among the other groups. This table is therefore disregarded in making up the weighted average of the total cases. Note the close similarities between the final figures for the entire group and for the especially selected anemia cases, as regards hemoglobin, red corpuscles, and leucocytes. The relative advance in the anemic cases, particularly as regards red corpuscles, was greater simply because the start was made from a lower level. With the selected group as with the entire group of unselected cases, the result was the bringing of the average at last to the level of approximate normality. Considering the variety of pathological conditions involved, these figures furnish a very striking verification of the theory of the protein response as deduced from my earlier observations and repeatedly published. Not one of these patients received a dose of iron or arsenic.

The tendency of the proteals to normalize blood conditions is evidenced in each of the tables here summarized. It is made a little more tangible if we note that, of the 113 cases, 42 were men and 71 women; recalling further that most haematologists estimate the normal red corpuscle count lower in females than in males. Some observers estimate the normal average count in women as low as 4,500,000. If we were to strike a compromise and consider 4,750,000 as the natural average for women, retaining the generally accepted estimate of 5,000,000 for men; a simple computation would place the normal average for this group of patients at 4,842,925. It will be seen that the average count before treatment fell short of this by 205,516; whereas the average count after treatment exceeded the normal by 65,181. In effect, then, the result of the treatment of this conglomerate group of cases for an average period of 130 days was to raise the red cell count to high normal—a typical protein response.

This result is illustrated even more directly by a computation which shows that the after-treatment average count of red corpuscles for the entire group of male patients was 5,161,034; and for the entire group of female patients, 4,854,020. Such statistics, covering entire groups of unselected cases, have unequivocal import. They are in gratifying accord with the published results of my earlier studies of the protein response.

The equally characteristic normalization of the leucocyte count is obvious at a glance; showing how radically and fundamentally this true protein response differs from the leucocyte-stimulus of a bacterial invasion or a vaccine inoculation.

Notwithstanding the striking character of the evidence presented by these figures, it should be emphasized that the modification of enzymic properties is probably more important than bare numerical change, although the two usually go hand in hand. A study of this aspect of the blood response, and of the equally important modifications of the differential leucocyte count will be made in another connection.

2. New methods of extraction of proteins, with reference to the varied qualitative and quantitative response of the unbroken protein molecule and of its successive decomposition products, including the ultimate amino-acids.

3. Tests to determine whether water-soluble vitamines and the mineral salts in the proteal

extract as at present made have any share in the therapeutic effects. Two lines are involved: (*a*) Feeding experiments with animals; and (*b*) the therapeutic use of extracts from which the proteins have been removed.

4. Studies of basal metabolism as influenced by protein injections. Our group of 22 very anemic patients showed an average increase of 13 per cent. hemoglobin and more than a million (28.4 per cent.) red corpuscles. Such histological changes should have measurable energy-equivalents. Can these be demonstrated; and if so will such demonstrations enable us to determine readily the relative efficacy of different proteins in promoting nutrition?

5. Observations regarding modifications of the blood conditions as to: (*a*) opsonic index, (*b*) enzyme titer, (*c*) specific gravity, (*d*) uric acid, and (*e*) total nitrogen in response to protein injections. Can chemical methods advantageously check and supplement histological and clinical findings? Questions as to immunizing possibilities and the nonspecific protein treatment of acute infections are obviously involved.

In the investigation of these open problems, as in all other departments of study of proteal therapy, theoretical or practical, I welcome the cooperation of professional colleagues everywhere. The products and the resources of my proteal laboratory are at the disposal, as heretofore, of all regularly qualified practitioners, and of Boards of Health, hospitals and clinics, and ethical laboratories public or private anywhere in the world.

104 East Fortieth Street.

"GROUP" MEDICINE—THE MEDICINE OF THE FUTURE.*

By J. Rawson Pennington, M.D., F.A.C.S.,

Chicago.

For many years past the business world has seen the value of organization, witness the formation of the Standard Oil Co., the Steel, the Tobacco, and other trusts galore, yet the medical profession with its usual conservatism has held aloof. At last there is considerable evidence that attempts are being made to overcome this inertia; I know of gratifying success attending an effort of this kind in a community of Middle Wisconsin, and I read lately a statement that "Fifteen Oshkosh physicians purchased a large apartment building in the heart of that city, and will have offices there, organizing the Oshkosh Clinic, which has been incorporated."

Furthermore, I know of another successful effort in North Dakota, and these will speedily be increased, judging by the frequent news items, such as: "The Baker Clinic was incorporated with a capital stock of $50,000, and with the expressed purpose of conducting a general medical practice and surgery." "The Clinic Holding Co. filed articles of incorporation. It has a capitalization of $100,000, and is empowered to hold real estate and personal property for the purposes of holding clinics and to carry on a general practice." "Drs. ——— have associated in practice, and the entire second floor of the Citizen's State Bank Building is being remodeled for their accommodation."

The wide spread of the idea can be judged by the fact that the items just quoted refer to localities so far apart as Oregon, Kentucky, and Minnesota. If any further evidence were needed we have it in the numerous advertisements in medical and lay journals, such as: "Oral surgeon wants to join group of specialists." "Wanted men specializing in anesthesia, roentgenology, ——— for a clinic which is being formed."

It is noteworthy that all these enterprises so far are situated in towns or small cities. I know of no attempts in the larger cities, and would be very glad to see such inaugurated.

There are naturally two aspects of this idea of "group" medicine—that from the patients', and that from the profession's standpoint; but before an audience of this nature, I shall, of course, devote most of my attention to the advantages from a professional point of view.

For a concrete example of the possible benefits, with due apologies, I select my own work as being most familiar to me, though the remarks with some modifications are equally applicable to other specialties or to practice in general.

Scarcely a day—I was going to write an hour—passes without my needing collaboration from the internist, the urologist, the oculist, or other fellow specialists; or from the laboratory and the *x*-ray worker. Now in the large office buildings in the loop district of Chicago, many specialists are available under the same roof, but this generally necessitates an elevator trip for several stories from one's own quarters. However, the nearest of the *x*-ray outfits to me is at the other end of a city block, down eleven floors and up fifteen—a long way for patients to go in unpleasant or stormy weather, to say nothing of some impediment to locomotion. How much more agreeable and convenient it would be to direct the individual to the next room, one a little further down the hall, or perforce at the extremes of a story above or below. Even if one is fortunate enough to have an office in the same suite or building with the *x*-ray men or other special workers, such arrangement is liable to be abruptly terminated by the changes so common in metropolitan centers, generally brought about by insufficient room. In the case of the *x*-ray man, for example, who may have our plates in store, or has provided himself with some unusual type of apparatus for our special work, we as a rule choose to seek him in his new location even though with more trouble, than to form new connections, may be under the same roof.

This "group" method will lead to more careful, hence better work. I fear there is some need for this, judging by the figures of Karsner, Rothschild, and Crump. They investigated the findings at necropsy in 600 cases as compared with the clinical diagnosis in two hospitals in a city—Cleveland, well known for its medical investigation and teaching—and found the gross error (of omission) was 8 per cent., and the minor error (of omission) was 60 per cent. To be sure, many of the minor errors disclosed (*i. e.* when the affected organ was properly diagnosed) had no influence on the treatment of the case or its outcome. But they claim the improvement of clinical medicine depends on an in-

*President's Address at the Twentieth Annual Meeting of the Ohio Valley Medical Association at Evansville, Ind., November 11 and 12, 1919.

creasing accuracy of diagnosis from which a more rational therapy can be adduced.

In a recent paper I referred to several of these diagnostic mistakes, but shall cite only two: A man had been operated on for ischiorectal abscess, four years previous and again a year previous, and healing had never taken place. I found the numerous anal and rectal fistulæ were kept up by necrosis of the sacrum, upon removal of which and proper attention to the fistulæ, the wounds finally closed.

The other instance shows I am not to be outdone and also make mistakes: A patient with syphilis had a colostomy performed, and a year later excision of the rectum by the abdominoperineal route. There was a short segment of the colon beyond the artificial opening; this was friable and was not removed on account of the woman's condition; merely closed at the distal end. Fecal matter passed into this segment from the opening for the colostomy, finally the feces escaped into the peritoneal cavity and out through the perineal incision and a fistulous tract in the posterior vaginal wall. The woman had periodic attacks of pain in the region of the stomach, which, because of the specific history, I diagnosed, as did several consultants, as gastric crises. Nevertheless, later on I found the crises arose from feces accumulating in the vaginal fistula, and ceased as soon as removal was made of this segment of the bowel.

The refinements of modern diagnosis call for employment of various instruments of precision, the use of which is not easy or understood by all, regardless of the amount of time required. With a stethoscope, for instance, I generally ascertain the presence of a valvular lesion, though having but a bowing acquaintance with the electrocardiograph or string-galvanometer, I should be at a loss to manipulate them.

Formerly the professional standard recognized by law was ordinary care and reasonable skill. But in an article a year ago by Mr. Peterson, a member of the legal profession of Minnesota, we learn in that State the standard has been modified and extended. "If," he writes, "the standard of professional skill was low in the community, or if the physicians possessed all the skill there was, because he was the only practitioner, the obligation of the law was met." In the case in question, one of fracture, adjudicated not long before, "the Court held that a surgeon living in Carlton, was in the community of Duluth, that medical associations frequently met in the larger centers, where the skill and learning of the profession were set out, and for the purpose of the standard of skill, it was the duty of the physician and surgeon to keep in touch with the doings of medical associations and the published contemporaneous literature of the profession."

The public at large is gradually learning of the necessity for radiograms in fracture cases, and of examinations of the sputum in chronic coughs, of the stomach contents in gastric disorders, or of the urine in vesical or renal disturbances; and the prompt use of such diagnostic measures may be important from a medicolegal standpoint. The community at large is, unfortunately, not yet convinced of the necessity for necropsies to benefit their fellow men and women, though considerable progress is being made of late in this respect.

After all, the dollars and cents side of the question is the most convincing. Here I can see nothing unfavorable. A "group" method presupposes a business manager, who looks after the equipment, supplies, financial details, etc. It is useless to expect a practitioner harassed with the struggle to support his family and himself, and staggering under a financial burden, to keep his cerebral activities at a sufficiently high level to do the best for his patrons. With the plan I advocate, there should be an assured income, even though small in the beginning, which will in time provide protection for his family, should sickness interfere with his activities, as well as provision for eventual retirement due to age. Again, there should be by this plan less difficulty as regards both time and money, in arranging for vacations either for recreation or for visits to centers of medical activity and teaching.

The old type of practitioner who, to use the words of his admiring patients, "never sent in a bill," is extinct—or should be. That storehouse of wisdom tells us "The laborer is worthy of his hire," and so is the doctor. The butcher, the baker, and the candlestick-maker expect the medical profession to pay, though it is too often the case that such tradesmen are by no means prompt in remunerating their own medical advisers.

Nearly a century and a half ago, Thomas Paine wrote of the "times which try men's souls." But the period he referred to—the day of the Boston tea-party, of Paul Revere's ride, and the immortal Declaration, was as naught when contrasted with the industrial unrest of the present and near future. Society as a whole bids fair to be organized, and the medical and other professions and callings must be affected.

It looks as though health insurance in some form or other is bound to come. A bill to this effect introduced at a recent session of the New York legislature failed to pass, though the governor of that State, who should be in a position to know, asserts the same or a similar bill will be introduced again, and passed in his opinion. Once such a bill passes, it will ultimately become a law in other commonwealths, for States have a peculiar tendency, like the proverbial flock of sheep, to follow the leader. The outlook is so threatening that the members of the profession in Buffalo and vicinity have formed a "Physicians Protective Association" to fight against similar attempts. However, I am afraid such efforts will have no more effect than that of the legendary Mrs. Partington to sweep back the billows of the Atlantic with a broom.

Another instance of this tendency is on the large railroad systems. Several of those in the Middle and Far West have for years maintained Hospital Associations to care for their injured employees. A few also provide for sickness as well as injury, and some of the bills introduced into Congress dealing with reorganization of the roads when they are returned by the Government provide for compulsory hospital associations.

A possible substitute is something on the cooperative plan. Many years ago the employees of a large manufacturing establishment in Chicago established such a plan for themselves and families. It ran along for some time, but I understand has been taken over by the officers of the establishment

itself. There have also been several more or less long-lived societies or companies, the members of which paid so much per annum for medical care and drugs for each member of the family per year. Though I recall but one still surviving.

What is in store for us under compulsory health insurance can be seen from the experience of the profession in England. When anything perturbs the average Englishman he writes a letter to the London *Times* signed "Pro Bono Publico" or "Taxpayer," but the physician rather chooses the *Lancet* or *British Medical Journal*. After the celebrated "panel" arrangement of Lloyd George went into effect (1912) one wrote an indignant letter to the effect the first crowd of applicants was so great his modest establishment could not contain them so they overflowed onto the front steps and the street, and mussed up the carpet in the hall so it had to be replaced. It must be acknowledged in fairness, however, that some practitioners in working communities admit their professional income is larger and more certain under this "panel act."

Finally what will accrue to the Science and Art of Medicine under this "group" method? Some months ago I addressed a letter to our Governor, Hon. Frank O. Lowden, advocating the establishment of an "Illinois Foundation for Research, Medical Education, and Sanitation." The suggestion was made that the State, county, and other hospitals should be organized into a State Hospital organization, maintaining reciprocal relations with each other. The management of the resources of the individual hospitals to remain under local direction; but the scientific and clinical work should be under State control for scientific purposes and for the further purpose of the diffusion of higher medical knowledge. It was pointed out that it is universally conceded the teaching hospital is the best for the patient, the doctor, and the public.

This medical organization should include a department of rural and city sanitation also. The State should appropriate sufficient funds to found a medical research laboratory, placing it in charge of a competent director, whose professional attainments, fitness, and skill are unexcelled. This done, the State of Illinois will have, at a comparatively small outlay, the most comprehensive Foundation for Research, Medical Education and Sanitation in the world.

Leech also pleads for "a cooperative institute devoted to purely scientific drug research, and governed in such a manner as to inspire confidence in its humanitarianism and unbiased judgment. . . . The hopes of American men of science are for a monumental research institution—cooperative with all the allied professions."

Standardization is the order of the day. In the class of diseases in which I am especially interested, taking such a common ailment as piles, in spite of the thousands, yes, tens of thousands of operations performed, there is little agreement among surgeons as to the best type of operation, the after-care, and so forth. Quite recently I proposed to some of my fellow-workers to pay visits to various other specialists, watch the work, and follow up each patient long enough to ascertain the end-result; and then, after due consultation, see if we could not agree on a given and definite standard.

This and innumerable other debated points could be settled in a comparatively short time by a sufficient number of "group" workers. There would have to be some central office, say in each State (or possibly for several States) to tabulate and publish the information available.

In conclusion I am not sure, nor do I claim, that "group" medicine would prevent that trend to paternal legislation, just alluded to, but it seems to me many or all of the disagreeable features might be eliminated.

EYE AND EAR SYMPTOMS IN BASAL CRANIAL INJURIES.*

By L. D. BROSE, M.D., Ph.D., F.A.C.S.,
EVANSVILLE, IND.

For the proper interpretation of injuries at the base of the brain, recognition of the eye and ear manifestations is often of the greatest importance and only through cooperation of the surgeon and oculist and aurist is it possible in certain cases to preserve the sight and facilitate recovery of the patient. The eye symptoms, as a rule, are not the result of fracture displacement or the trauma directly, save in gunshot injuries, stab wounds, and depressed fractures or penetrations which lacerate and tear the brain substance, but arise through brain compression from hemorrhage, brain edema, and inflammatory exudate. We term this latter indirect injury. Why indirect injuries are so badly tolerated is readily comprehended when one reflects that the cranial cavity is completely occupied by the brain and its membranes and that the bony cranial walls are rigid and unyielding so that volume increase can occur only where there has been brain compression. The optic nerve in reality is an extension of brain tissue, enclosed sheath-like by the brain membranes and in such a way that the vaginal space which surrounds the nerve as far as the eyeball is in direct communication with the intracranial lymph spaces. The construction of the eyeball may roughly be likened unto that of the cranial cavity, in that it too is enclosed by the unyielding sclera, a firm and unyielding connective tissue membrane with but a single opening and this constructed sieve-like, through which the optic nerve fibers and its vessels make their entrance and exit. An increase in tension of the cerebrospinal fluid must exert a corresponding rise in pressure upon the optic nerve and this is followed by interference in the circulation from the eye with strangulation at the unyielding porous opticus, as a result of which edema of the optic nerve papilla arises. Papilledema then is an early and valuable diagnostic symptom in many basal injuries and the general surgeon should have a competent oculist make repeated ophthalmoscopic examination of the eye fundus in such patients, since if the papilledema is permitted to continue unrelieved optic nerve atrophy follows and the patient, although he makes a recovery, does so with the loss of his eyesight. One-sided optic nerve lesion is due in most cases to injury or fracture involving

*Read at the twentieth annual session of the Ohio Valley Medical Association, held at Evansville, Ind., November 11 and 12, 1919.

the bony optic foramen in the sphenoid bone, or to compression of the optic nerve at this point by hemorrhagic extravasation. In these cases the ophthalmoscope during the first three to five weeks may disclose no evidence of the lesion. The field of vision, however, where the sight has not been wholly destroyed, is apt to disclose defect, such as concentric contraction or a quadrant defect. Sooner or later the nerve head will disclose descending atrophy which the oculist can recognize. Hemorrhage into the sheath of the optic nerve in basal fracture is well known to the ophthalmologist and according to Wagenmann due to rupture of a vessel in the optic canal or through the escape of intracranial blood along the optic nerve sheaths. The causal traumatism may be slight but the site is usually in the frontal or orbital region. Where the affected eye is rendered totally blind the pupil fails to respond to direct light stimulation; likewise there is absence of consensual pupillary reflex in the other eye. On the contrary direct stimulation of the seeing eye causes pupillary response in both eyes. Because of this preservation of the consensual pupillary reflex the pupil of the blind eye remains the same in size as that of the seeing eye. During the late war many cases of hemianopsia, or half-sided loss of vision have been encountered, the result of injury to the cortical visual centers on the opposite side of the brain. Involvement of the cortical visual centers on both sides may occur and produce bilateral blindness. This is usually followed by recovery of some sight in one eye about the fixation point. Hallucinations in these patients may be complained of in the blind halves of the visual fields indicating that the visual memory center continues active. Visual aphasia in some form may also be encountered, especially when the lesion is one involving the left occipital lobe. Lesions of the central optic pathway and transcortical tract likewise give rise to homonymous hemianopsia in the differentiation of which the hemianopic pupil reaction may be used. Where the chiasm is wholly destroyed complete blindness follows in both eyes. Partial chiasmal destruction may produce blindness in one eye with temporal hemianopsia in the other eye: or a bitemporal or a binasal hemianopsia. Chiasmal injuries are prone to occur with fractures involving the middle fossa while occipital injuries are more likely to produce lesion in the cortical centers. In wounds involving the occipital bone papilledema occurs much more frequently than in other cranial injuries. Secondary optic nerve involvement, after traumatism, may result through infection from the ear, the paranasal cells, meningitis, brain abscess, or pulsating exophthalmus. According to Uhthoff rapidly developing neuritis or choked disc after fracture of the base of the skull is of serious prognostic omen. In the localization of basal skull injury the history of the patient and nature of the injury together with the intra- and extraocular manifestations should be considered. The motor nerves of the eyes may be involved singly, collectively, or in pairs. The sixth nerve is probably oftener involved than the other eye nerves and the following is an interesting example of double abducens palsy:

Joseph H., æt. 40 yrs. and a resident of this city, consulted me July 22, 1908, with the following history: On April 25 preceding he was struck by a street car, rendered unconscious, and taken to St. Mary's Hospital. When he became rational he noticed something wrong with his eyes. I found both eyes strongly turned in with inability to turn either eye outward. There was no intraocular lesion and he had vision 15/xxx both eyes. Nine months later the paralysis of the external recti continued unchanged. Because of the complete palsy and its persistence without improvement I look upon this as a lesion of both sixth nerves in the posterior fossa of the skull, rather than of their nuclei.

It is established that sixth nerve palsy may be caused by fracture of the base of the skull without coma, without paralysis of other cranial nerves, or other usual symptoms of basal fracture; this because of the close relation the nerve bears to the margin of the sella turcica and the pyramid of the petrous portion of the temporal bone. Monolateral sixth nerve palsy with hemiplegia of the opposite side of the body points to lesion at the posterior margin of the pons; the more so if the facial nerve is likewise involved on the same side as the eye paralysis. Paralysis of the sixth nerve with associated palsy of the facial and trigeminus points to fracture of the petrous pyramid and the auditory nerve may be injured when the line of fracture passes through the internal auditory meatus. In all oculomotor paralysis we should think primarily of a basal injury. When the third and sixth nerves are simultaneously paralyzed there may be fracture of the petrous portion of the temporal bone since the two nerves lie close together at this point. Oculomotor palsy with palsy of the opposite side of the body points to lesion in the cerebral peduncle. If the line of basal fracture be of such nature as to lacerate the third nerve near the anterior margin of the pons, bilateral third nerve palsy may result while the optic tract escapes since the two motor oculi nerves are in close proximity at this point. Where all the external ocular muscles are paralyzed we speak of the lesion as ophthalmoplegia externa with localization of the injury in the third nerve nucleus in the floor of the fourth ventricle, in the aqueduct of Sylvius, and in the posterior part of the third ventricle. Nuclear third nerve palsy is usually bilateral with symmetrical muscle involvement but preservation of the elevator of the lid. With the line of fracture through the sphenoidal fissure and the optic foramen you find unilateral third nerve palsy with optic nerve involvement. The condition of the pupil alone is of but slight diagnostic value in cerebral injury since it may be contracted, dilated, or of normal size. The rule, however, is that with increased intracranial pressure you find the pupil small; with continued pressure the pupils may dilate. A unilateral dilated pupil in basal fracture is of some significance in making a diagnosis of intracranial hemorrhage in the middle fossa on the same side, providing you can exclude local traumatism, which it is well known is capable of producing unilateral mydriasis through small tears in the iris tissue. An injury causing rupture of the internal carotid artery at the cavernous sinus may implicate the third, the sixth, the ophthalmic division of the fifth, as well as the optic nerve. In such cases you have pulsating exophthalmus, swollen eyelids, distended conjunctival veins with chemosis conjunctiva. In isolated fracture of the orbital wall the hemorrhage may diffuse itself through the orbital

tissues and give rise to conjunctival ecchymoma. Through pressure injury palsy of the orbital nerves and extraocular muscles may occur. The pupil and ciliary muscle as a rule remain intact as was the case in the following patient:

H. H. B., æt. 64 years, was thrown from his buggy May 18, 1914, by his horse running away. He struck the earth violently with the right side of the face, producing a depressed fracture of the lower orbital rim. I saw him the following day at the Hayden Hospital and found the right eyeball fixed, the pupil dilated but sluggishly responsive to light. Vision in the eye was reduced to light perception. Ophthalmoscopic examination disclosed no intraocular lesion. June 17 vision had improved to 15/lx and later with +1.00 s. +0.50 cyl. ax. 90, he saw 15/xx. He retained permanently double vision, which I attributed to palsy of the inferior oblique and the external rectus, since the eye motility was restricted in the upward and outer plane.

The third nerve and the facial nerve are not infrequently injured by forceps during difficult instrumental delivery of the child. Ptosis and lagophthalmus are seen in these cases. A lesion of the trunk of the third nerve or of its cortical or nuclear centers may at times likewise produce ptosis. Cerebral spastic palsy in the child is frequently the result of an intracranial hemorrhage following difficult labor. Primary unilateral optic nerve atrophy in the child is not the result of a constitutional trouble but attributable to pressure injury to the nerve of sight from hemorrhage peripheral to the chiasm. Ophthalmoscopic examination should never be omitted in these children, and if papilledema or optic neuritis is found, spinal puncture is to be practised, followed later when positive increased intracranial pressure is established by subcortical decompression. Traumatic neurosis may result when the injury has not occasioned physical trauma. The clinical picture of these cases is manifold and comprises sudden deafness and dumbness; ocular spasms; palsy of the lower branch of the facial nerve, while the portion enervating the orbicularis palpebrarum escapes; functional contraction of the visual field without recognizable ophthalmoscopic change in the fundus; amaurosis; fifth nerve involvement giving rise to circumscribed anesthesia and disturbed corneal and conjunctival reflex. It is the central cortical areas which subserve voluntary movement in the waking hours that are affected and not the lower nuclei and nerve trunks. This is evidenced by the ocular palsies being those of associated movement or conjugate. The following case is of interest from a medicolegal standpoint and demonstrates the care required in interpreting these injuries.

Mrs. E. W., æt. 22 years, was referred to me by her legal adviser with the following history. Six months previous she was injured over the right side of the head in an automobile accident and in consequence claims damages on the ground of injury to her sight and nervous system. I found vision in the right eye the counting of fingers at eight feet. Vision in the left eye 15/cxx. She has a scar over the anterior portion of the right temple but this she stated is the result of an injury in childhood. The auto injury has left no evidence externally. The ophthalmometer shows marked astigmatism in both eyes. Ophthalmoscopic examination corroborates the presence of astigmatism and reveals in addition in the right eye a macular hole with its upper and inner and lower and outer borders slightly pigmented. The floor of the hole disclosed white sclera. There were no vitreous opacities and the left fundus was not diseased. The visual field in both eyes disclosed marked peripheral contraction. With the following correction vision was improved. Right eye +2.00 cyl. ax. 120 15/clx; left eye +1.50 cyl. ax. 90 15/xl. She had never worn glasses previous to this accident, and this of itself is evidence that she never knew how defective her sight was nor how well a normal eye should see. Certainly the astigmatism has always existed and cannot be of recent development since the cornea is clear and without evidence of disease. Because of this and the general appearances of the macular hole which did not look as of recent formation, and of biweekly recurring head pain of which she complained, I gave the opinion her claim for damages should be based on traumatic neurosis and not organic eye injury.

Ear lesions, the result of cranial injury, may be confined to the external ear or involve the middle or inner ear. The locality and nature of the external ear lesion is largely determined by the site of the violence. Thus a fall on the top of the head may be followed by fracture of the superior wall of the meatus; striking on the back of the head by fissure of its posterior wall; while a knock-out blow to the lower jaw may cause a fracture through the anterior wall of the external meatus. Direct violence may cause depressed fracture limited to the outer table of the mastoid. The severe injuries are not apt to be so circumscribed, but extend to the middle and the inner ear, producing rupture of the ear drum and severe bleeding at the ear. Such hemorrhage, however, does not necessarily imply drum rupture since it has happened that the drum remained uninjured with fissure through the superior wall of the outer meatus and this afforded egress to the middle ear hemorrhage. Injury to the chorda tympani nerve is followed by impairment of taste in that portion of the tongue which this nerve supplies. Many of the severer injuries of the middle and posterior cranial fossæ are complicated by fracture of the pyramid or labyrinth of one or both ears. Continued ear hemorrhage or the loss of cerebrospinal fluid points strongly to such injury during the unconscious stage. With the regaining of consciousness deafness is found with nystagmus, subjective noises, dizziness, and nausea. In labyrinthine fracture associated palsy of the facial nerve is seen in something like one-half the cases. The fifth nerve may be injured with fracture near the apex of the petrous bone. Other cranial nerves that may show injury are the sixth, fourth, and third nerves. The hearing may be lost or impaired without fracture of the temporal bone in which case the lesion is one of concussion or hemorrhage into the labyrinth or internal auditory nerve, or again the lesion is one of the sound conducting apparatus with ankylosis of the stapes in the foramen ovale with implication of the vestibule. The last mentioned lesion is a unilateral one and explained by a sudden traumatic compression of the air column in the external ear spending its violence on the ear drum and the hearing ossicles. Characteristic of such lesion is that the hearing loss may be for certain tones or a subjective modification of certain tones. About one-half of the patients with severe brain injury and fracture involving the inner ear, die during the first two days. The subsequent danger lies in meningitis, which is prone to occur during the succeeding four weeks, or brain abscess which is a much later complication. It must not be overlooked, however, that an apparently trivial fall on the head without fracture

is capable of producing grave intracranial hemorrhage or hemorrhage in the inner ear that may result in deafness, blindness, and death while a severe injury of which the following is an instance may end in complete recovery.

Chas. B., of middle age and a railroad conductor, was standing on the rear of a coach in the station at Carmi, Ill., when his train was bumped into by another and he was thrown violently to the ground, alighting on the top of the head. He was picked up unconscious and brought to St. Mary's Hospital, Evansville, where I saw him with the late Dr. P. Y. McCoy. There was bleeding with loss of serous fluid from the left ear during the succeeding forty-eight hours, while unconsciousness continued two weeks, yet the patient made an ultimate recovery and quite recently told me the hearing in the injured ear was better than in the right ear which was not injured.

Treatment: Bullets or foreign bodies located by the probe or *x*-ray in the mastoid or middle-ear air spaces should be removed as early as possible since they are incapable of becoming encysted and sooner or later excite reactive inflammation and suppuration. During severe shock one had best defer operative interference until reaction occurs. Likewise a patient in a stage of collapse with Cheyne-Stokes breathing and greatly increased pulse frequency should not be operated upon. In general, treatment should have for its objective the elevation of depressed fracture, the relieving of shock, the arrest of hemorrhage, the prevention of infection, and controlling cerebral pressure. For the latter an early resort to lumbar puncture should be had and the intracranial pressure estimated by the spinal mercurial manometer. The amount of spinal fluid to be withdrawn will depend upon the rapidity of flow through the cannula; in general one and one-half to three fluid ounces may be taken. The eye fundus should be repeatedly examined and if the papilledema continues a subtemporal decompression is to be made.

501 South First St.

MODERN TREATMENT OF TUBERCULOSIS.*

By R. C. KIRKWOOD, M.D.

ALBUQUERQUE, N. M.

MAJOR MEDICAL SECTION OFFICERS' RESERVE CORPS, U. S. ARMY; FORMERLY CHIEF OF MEDICAL SERVICE, U. S. ARMY GENERAL HOSPITAL, FT. BAYARD, N. M.

When the above subject was assigned to me I wondered if it were proper to use the word "modern." I wondered if our treatment of the tuberculous had been improved upon and modernized in any way. Upon consideration, I believe that it has, especially with regard to one important factor which I shall stress later. There have been many changes in the treatment of tuberculosis since my day as a patient and my subsequent entry into the work as a physician. This, that, and the other drug has been loudly heralded as a specific and later as silently abandoned. Various serums have been used for a time and discarded. Tuberculin has never proven as helpful as we hoped it would be. The days of "stuffing" patients are over, and we have adopted a more rational dietetic régime. When I first entered this work patients were advised to go West and "rough it" and to practise deep breathing. To-day we insist upon long periods of rest in bed while the disease is active, and in a certain number of cases we completely inhibit the motion of the lung most affected by the use of artificial pneumothorax. Let us then consider briefly the elements of the modern treatment of tuberculosis. What we seek by treatment is not so much to find agents which will destroy or inhibit the tubercle bacillus as to help our patients restore their own immunity, for results can only be secured where there already exists an immunity which is capable of reinforcement.

Some patients get well in spite of gross neglect of treatment; others with what appears to be a less severe lesion can be cured only by rigid adherence to the principles of treatment for long periods, and still others with apparently small lesions die from tuberculosis which progresses unfavorably from the very outset. No matter what treatment you may adopt the result in each individual case depends fundamentally upon the degree of immunity which the organism is capable of attaining.

"In tuberculosis we prescribe, not medicine, but a mode of life." It is a simple matter to write prescriptions but it is difficult indeed to influence the patient so effectively that he will be willing to change entirely his mode of living and persevere in the new way for months, perhaps for years, often through his whole life. To do this requires much patience and zeal and the physician must have faith in the treatment he prescribes, must really believe what he says when he strives to influence his patient. The physician must have a knowledge of why certain things are necessary in treatment and must be able to present these reasons so convincingly that the patient will receive them and be guided by them.

For a long time we were taught that the tripod of treatment was rest, good food, and fresh air. In recent years many of us have added a fourth desideratum which is happiness, a contented mind. This fourth element is receiving more attention as times goes on. Much stress was laid upon it in the treatment of tuberculous patients in the Army Hospitals during the recent war. We had our Morale Officers and Reconstruction Aides whose sole duty was to supply or attempt to supply this element of treatment, without which the other three elements will fail of success. The psychical side of treatment is that which is most neglected, yet in it the most notable successes are attained.

Some physicians seem to consider it necessary to keep up the patient's faith in the treatment by the use of drugs or serums which are given as placebos, not because of their therapeutic value and they will perhaps tell you that, as the course of the disease is long, it will be necessary frequently to change the drugs employed in order that the patient's hope may be kept alive. This is a device of the faint-hearted and pessimistic, they are trying to deceive the patient and must inevitably fail in the long run. The physician with faith and zeal will endeavor to bring the patient's will to command; he will encourage optimism and perseverance, a resolute putting away of doubts and fears, a stout-hearted determination to endure cheerfully a monotonous existence. The patient to be successful must be a good deal of a philosopher and must cooperate with the physician, for next to a good immunity and a good physician, the third most important consider-

*Read before the Thirteenth (Indiana) District Tuberculosis Conference, Plymouth, Indiana, May 22, 1919.

ation is faith in the physician and willingness to cooperate with him.

Rest.—The influence of rest in abating the severity of inflammatory processes is well known. Rest is especially important in tuberculosis in order to lessen the volume of pulmonary lymph and so lessen the danger of extension of infection to healthy portions of the lung. Rest is necessary to promote the formation of fibrous tissue, scar formation, and the walling off thereby of the tuberculous focus. In tuberculosis the formation of fibrous tissue is caused by the irritation from the toxins of the disease. If the parts are at rest the irritant will be localized within a certain zone, and dense fibrous tissue will form at the limits of this zone, whereas if the parts are in active motion there will be diffusion of the irritant and as a result scattered and less dense, less well-defined fibrous tissue will be formed. Rest is necessary for the recuperation of the vital forces of the body and for the strengthening of the weakened nervous system. The tuberculous patient is neurasthenic, he expends nervous energy with the utmost prodigality and without adequate reason. It is because of this that patients sometimes find it so hard to relax completely and remain quiet in bed. And when they do fully relax and realize their weakened condition they so often misinterpret this and believe that rest in bed, instead of simply revealing their weakness, has caused it. Rest as we use the term in the treatment of tuberculosis means, of course, only relative rest, but the more nearly the patient can approach a state of absolute rest the better are his chances for recovery. Colonel Bushnell, Chief of Tuberculosis Work in the Army, in the most able article on treatment of tuberculosis ever written in English, suggests that patients assume the attitude of the "jelly-fish," which bobs about hither and thither with the waves, and speaks of the proper method of resting in bed as "jelly fishing."

The best way to relax the muscles is to expire deeply, letting the muscles go during the process, hitting the bed hard, as the saying is, and then holding the position gained in the following inspiration.

The best position for relaxation is supine at full length with arms and legs everted. Some patients do not know how to rest even lying down, they are constantly in motion, and for such patients lying in bed is exercise and not the best form of exercise. Sitting is an artificial posture which requires the constant contraction of certain groups of muscles. Therefore, a patient is not at rest when sitting but is exercising, a bad form of exercise, also.

The favorable effect on the lung condition of the onset of a Pott's disease of the spine, or that seen in patients who have suffered fracture of some portion of the lower extremities, is well known and is due to the fact that these conditions make complete rest in bed absolutely necessary, make it impossible for the patient to do otherwise than lie still in bed. The patient must be taught the necessity of not interrupting the treatment on any excuse. "The tubercle bacillus takes no days off, therefore the patient must take none."

In most instances it is inadvisable for patients to visit their homes or at least to do so with any frequency, for there it is impossible to secure the needed rest. Patients always over-exercise and come back definitely worse as a result. They are oftimes exposed to acute respiratory infections which will assuredly prolong their convalescence and possibly endanger their lives. The writer agrees with Col. Bushnell, who objects to visits home, and says, "My philanthropy is of a sterner sort and demands that the great business of getting well shall suffer no diversion however pleasant."

Fresh Air.—Fresh air is almost as important as rest. As the term is used it implies out-of-door air, and as a rule this is what is to be desired. However, very ill and debilitated patients should not be permitted to endure the hardships of out-of-door life or sleep out in extremely rigorous weather. The difference between the air of a well-ventilated room and an out-of-door porch is not sufficient to warrant the exposure of this type of case. As in every other element of treatment, the physician must be sincere in his advocacy of fresh air; must be able to explain the reason for this to his patients in such a way that his patient will willingly accept his advice and cooperate. Patients should never be allowed to sit in heated, poorly ventilated rooms. In cold, damp, or foggy weather they should be kept in bed with sufficient covering to keep them comfortable and not allowed to congregate in their dressing or recreation rooms. Strictness of discipline with regard to this is very important.

While considering fresh air, the subject of climate suggests itself. It may be stated in passing that while, other things being equal, a climate which is favorable for a pleasant out-of-door existence for the greatest possible number of days out of each year, a region in which there is a maximum of sunshine and in which there is rather marked variation between night and day temperatures (such as one finds in the Rocky Mountain region and in the Southwestern States) is the most favorable for the tuberculous. But unless the patient can have *all* the other factors of value in treatment, the bettered climatic conditions will avail nothing, and he will do better in his home climate. Pottenger very aptly says, "It is better to make good use of a bad climate than bad use of a good climate." And so, unless patients can have in the more favorable climate opportunity for proper rest, good food and an abundance of it, fresh air in the open, unless they can be properly housed, have competent medical supervision, and, above all, be free from worry, they had better remain where they *can* have *all* these other factors even though climatic conditions do not seem to be so favorable. Climate is by no means so important a factor in treatment as we once considered it.

Food.—The food given to a tuberculous patient should be of good quality, properly prepared, plain, and easily digested. The diet should be mixed, a varied diet. But he should be given no more than one would give to a healthy man at rest, and certainly no more than he can digest without difficulty. The old-fashioned idea of "stuffing" the patient was the cause of many gastrointestinal disturbances which we erroneously ascribed to the disease. Food consumed at one meal should be entirely digested before the next meal is eaten. The best way to treat poor appetite is to omit one or several meals until a healthy, normal hunger develops. "He who

is a little ahead of his needs is never hungry." Col. Bushnell also says, "It is better to eat yesterday's dinner than to-mrorow's." It was thought that because of the lack of food tuberculosis would be very prevalent among French prisoners in German prison camps. But this was not so, and in cases having definite tuberculous lesions when captured the tuberculosis was not materially accelerated nor the area of involvement materially increased by the semistarvation incident to confinement in these camps. Col. Bushnell reports the case of an army officer who, in addition to tuberculosis had sprue and hookworm, and though his diet was, because of these complications, markedly deficient in both calories and nitrogen, his tuberculosis progressed favorably, and he secured a complete arrest. He finally recovered from both sprue and hookworm and has done duty many years without relapse. In another instance two tuberculous patients were shipwrecked and in an open boat for a long time without food except a few crackers and some water. When finally rescued they were very weak from lack of food, but because of the rest incident to inactivity (the sailors did all the rowing) in the boat during this time their chest condition was improved. The examination of these men just before they started on the voyage and just after their rescue was done by competent men, well known as tuberculosis physicians. Therefore, overfeeding is not indicated, and though patients should be well fed, if they have digestive disturbances the best way to treat these is by omitting one or several meals, and this can be done without unfavorable effect upon the tuberculous process. Much of the digestive disturbances so common during the days of "stuffing" patients and then blamed onto the tubercle bacillus was due to overfeeding, overtaxing a gastrointestinal tract below par at best, and patients vomited often simply because the stomach was over-filled, just as a bucket runs over when you put more water in it than it will hold.

Exercise.—When a tuberculous patient begins to exercise he has reached a danger point in his treatment. He cannot be too carefully watched. In case of doubt it is always safer to err on the side of too much rest. Exercise as a therapeutic measure in tuberculosis should be restricted to the chronic case, and the physician must be quite sure that he is able to determine the fact of this chronicity before he attempts to make such prescription. This determination of chronicity is a nice point and one which always taxes our best judgment, a problem which can be accurately solved only after years of experience in the observation of a large number of cases. The error most frequently made is to permit patients to exercise too soon and then to increase too rapidly the time allowed for exercise. Walking is the best form of exercise to begin with. This may later be supplemented by light games, *e. g.*, croquet, and, later still, golf, carrying various weights in a basket, digging with a shovel or spade, pushing a wheelbarrow containing gradually increasing loads first on the level and then up gradually increasing grades, thus by increasing the loads and the grade the amount of exercise may be increased slowly but almost without limit until the amount of exercise equals that one would do in the course of a full day's work. This is very important and because of the failure to recognize the importance of this our sanatorium results have not been lasting. We send patients back to work without "hardening them up" in preparation for active work in competition with healthy workers. The result has been that these patients soon "break down" again and return to the sanatorium worse than at the first admission. In speaking of the method of gradually increasing exercise by carrying various weights and pushing various loads up increasing grades, etc., I might explain that the method has been extensively worked out by Paterson of Frimley, England, who uses it as a means of stirring up some self-made tuberculin, autoinoculation, he calls it. The method is of distinct value but must be carefully used and the cases carefully selected. Much harm can be done by its improper use. Slight fluctuations of temperature following exercise should be disregarded, if the temperature returns to normal with a short period of rest. However, a patient whose temperature reaches 99.5° or above daily should not exercise, no matter what his general or pulmonary condition seems to be. Exercise is for chronic cases only, and its greatest usefulness is in "hardening up" patients before they are returned to their various occupations.

Psychic Treatment.—Without freedom from worry, without contentment, peace of mind, or whatever you may see fit to call it, but little, if any, benefit will be derived from the other fundamental elements of treatment. Happiness is as important a part of treatment (to my mind, indeed, the most important) as is rest, good food, fresh air, or anything else. The physician himself must be optimistic and must be able to impart optimism to his patients. Patients must be instructed not to discuss their symptoms with each other, they must be taught to control their emotions, they must be familiarized with the evil influences of worry, homesickness, and other depressing emotions. For those who do not yield readily to suggestion, who find it hard to be influenced by psychical treatment it is well to advise them that if they must worry and feel "blue" they select certain hours of the day during which they may feel as "blue" as they want, and during which time they may worry to their heart's content. This suggestion rarely fails to excite a smile, and it is quite evident that an emotion deliberately excited at a fixed hour will rarely be strong enough to be prejudicial. The physician should thoroughly understand the mental, the *human* side of tuberculosis, and it is my belief that none can so thoroughly understand this most important phase of the disease as one who has himself been tuberculous. Every effort should be made to keep the patient happy and contented and to provide for his amusement and diversion so long as this does not interfere with the other elements. To this end musicals, elocutionary recitals, motion picture "shows," "parties," amateur theatricals, etc., should be provided, lectures on travel, art, literature, and other subjects given, and good reading matter furnished in abundance. The air of an institution should be, as far as possible, dispelled and the sanatorium made to seem more like a great country estate at which staff and patients are sojourning together as one great family, one large, happy family, among the members of which the spirit of altruism

should prevail. The importance of the psychic side of treatment is becoming each day more and more recognized by a greater number of workers in the tuberculosis field.

Symptomatic Treatment.—The treatment of annoying symptoms in tuberculosis is important. On the other hand, one should be able to differentiate between those really demanding treatment and those of no importance. Every little ache and pain does not need medicinal treatment, psychosuggestion being the treatment indicated in this type of symptom. Cough medicine should be used sparingly but at the same time patients should not be allowed to exhaust themselves with the harrassing, nonproductive cough of the peribronchial infection. One must be able to judge when to use sedative and when expectorant cough mixtures. After hemoptysis sedative cough medicines should be used to full effect. However, much cough is unnecessary, and the patients can be taught to control this useless cough.

They can be taught not to exhaust themselves in an effort to raise an insignificant pellet of mucus, which, with a little patience and self-control, will be forwarded by the natural mechanism and readily ejected with but little effort. Cavities can be drained daily by posture, and much coughing thereby avoided. Overrule the idea that expectoration is infectious to the patient himself and must be gotten rid of. Disabuse the patient's mind of the fallacy that it is extremely dangerous to swallow sputum. Patients are sometimes kept in a constant state of nervous apprehension by such notions, which is most prejudicial. The tuberculous patient ascribes every slight unpleasant sensation to his tuberculosis. For him the pain in the chest always means pleurisy and every slight diarrhea raises the spectre of intestinal tuberculosis. However, the patient should report these symptoms to the physician and they should be given due consideration. If of no moment this should be explained to the patient to allay his fears.

Tuberculin.—The writer has too often seen serious harm come from the use of tuberculin to be enthusiastic about its use. Cases of active, manifest tuberculosis are rarely benefited by it and often seriously harmed. Those benign cases in which such excellent results are ascribed to its use are cases which will get well with just a little change in one's mode of living, and the result in these cases would likely have been as good or better without it. In certain selected cases of tuberculosis of the eyes, glands, and larynx, tuberculin carefully used in small doses seems to be of benefit. But it must be used by one trained in its administration. In the hands of the untrained tuberculin is a terribly deadly weapon. Because of this fact Col. Bushnell states tuberculin has no place in the therapeutic armamentarium of Army Tuberculosis Hospitals. Col. Bushnell very aptly characterizes its use in the benign cases referred to above by saying, "Tuberculin is most helpful to those who need help least." Unless thoroughly trained in its use, tuberculin had better not be used in treatment.

In conclusion, I desire to acknowledge my indebtedness to Col. George E. Bushnell, U. S. A., retired, from whose article, "The Treatment of Tuberculosis" (MEDICAL RECORD, May 11, 1918, and *The Military Surgeon*, June 1918), some of the matter in this paper has been taken.

MODERN UROLOGICAL ADVANCES AND THEIR EFFECTS ON RENAL SURGERY.*

BY A. G. RYTINA, A.B., M.D., F.A.C.S.,

BALTIMORE, MD.

PROFESSOR, GENITO-URINARY DISEASES, UNIVERSITY OF MARYLAND, COLLEGE OF PHYSICIANS AND SURGEONS.

I THOUGHT it would be of interest to the members of this Association to relate briefly some of our modern advances in urology, and to show what effect they have on kidney surgery.

Surgery in recent years has achieved many triumphs. Hardly any branch of this specialty, however, can emulate the results obtained by the modern urologist in renal surgery. The genito-urinary surgeon can explore the kidney, remove or repair it with a mortality of about two per cent. Contrast this with the series of 1118 cases collected and reported by Schmieden in 1902, in which nephrectomy was done for various conditions. The operations were performed from 1870 to 1900, and divided into three decades. The mortality rate in 1870 was 43.9 per cent., in the second ten years it was 26.9 per cent., and in the third 10 years it was 17 per cent.

These nephrectomies were by the lumbar route. The rate, when done by the abdominal route, was doubly higher, viz., 55 per cent. for the first ten years, 48 per cent. for the second ten years, and 19 per cent. for the third ten years. The average mortality by both routes during these thirty years was 35 per cent. To what is this tremendous improvement in the mortality rate at the present time due? Not to any special improvement in the operative technique or to the manipulative dexterity of the operators, but mainly to the careful preliminary study and the application of modern urological methods.

Let us mention briefly what these modern urological methods are. Of the greatest importance is the catheterizing cystoscope; next renal functional tests; then *x*-ray, pyelography; the bismuth and wax-tipped bougie; etc. Before we are justified in subjecting a patient to a kidney operation, several important conditions must be fulfilled. We must know, firstly, if there is another kidney present, for there are a number of cases on record of congenital absence of the kidney. According to Morris, the absence of one kidney occurs once in 2400 individuals. A more common abnormality is the so-called infantile kidney. Nephrectomy in either of these conditions would lead to the death of the patient.

Often in these cases the other kidney undergoes a compensatory hypertrophy and may be even painful, so that the general surgeon who thinks a painful, palpable kidney mass a sufficient excuse for subjecting the patient to an operation may have a rude awakening. More important, however, in this connection, is the determination of the unilaterality or bilaterality of the affection. I can better illustrate my meaning by citing one or two experiences:

E. had certain toxic symptoms and marked pyuria. The *x*-ray showed two definite shadows in the left kid-

*Read at the twentieth annual meeting of the Ohio Valley Medical Association, held at Evansville, Ind., November 11 and 12, 1919.

ney. The surgeon in charge of the case refrained from operation only when he was told a previous examination by a urologist revealed a bilateral infection of the kidneys. On examination we also advised against operation, because both kidneys were the seat of an extensive pylonephritis.

S. was first seen by Drs. Beck and Blake, who diagnosed a hypernephroma of the left kidney on account of the presence of a very large left kidney. The combined phthalein output was 15 per cent. We were asked to study this patient in order to see if he was a safe operative risk in view of the low functional output. On examination the patient showed polyuria and slight albuminuria; otherwise the urinary findings were negative. The right kidney, too, was slightly palpable. Catheterization of the ureters showed the phthalein output of the left kidney, viz., the one on which operation was contemplated, to have nearly three times the output of the other kidney. The diagnosis of bilateral polycystic kidneys was made and confirmed at the time of the exploratory operation.

It is obvious that if either of these cases had been nephrectomized, death would have resulted. Another theory of the general surgeon that I would like to explode is the point they mention that you can, if necessary, explore both kidneys and by vision and especially palpation easily detect the one which is the seat of a pathological process. I would like to emphasize, that it is essential to learn prior to operation the condition of the affected kidney, and if this study shows the need for removal of the kidney, then to perform nephrectomy even though surface appearances and feel appear normal. I have within the past few years seen several kidneys exposed which looked and felt normal, yet upon bisection after removal showed advanced and extensive tuberculosis.

I would now like to discuss briefly not only the diagnostic, but the conservative importance of pyelography. Pyelography may be defined as the introduction into the kidney, kidney pelvis, and ureter through the medium of the ureteral catheter some shadow-casting substance, and then taking an *x*-ray. By means of it we can often diagnose abnormalities, ectopias, as well as pathological changes such as new growths, hydronephrosis, etc. The relative position of a stone within the pelvis and substance of the kidney can often be ascertained without the need therefore of bisecting the kidney, as is often done, and thereby not only conserving renal substance but doing away with the danger of the serious secondary hemorrhage that so often follows nephrotomy for any cause.

One of the most interesting pyelographic experiences I have had is the following:

C. entered the Mercy Hospital with acute pains in the right side of the abdomen, for appendectomy. She was transferred to the genitourinary service by Dr. McGlannan, who thought the symptoms complained of by the patient were due to renal colic. She had had a number of previous attacks. The *x*-ray examination of the kidney and ureter were negative. The urinary examination was also negative. A pyelogram showed the upper ureter region bound to the lower kidney pole A diagnosis of Dietl's crisis was made, due to inflammatory adhesions binding the upper ureter to the lower kidney pole. At operation the above pathological condition was found, only it was due to an aberrant vein encircling the ureter and not to inflammatory adhesions. Division of the vein and replacing the kidney were sufficient to free the patient from any further attacks of pain.

Another great aid at the command of the urologist is the bismuth bougie and the wax-tipped catheter. It is surprising to me how frequently the *x*-ray man will report shadows as suspicions of ureteral stone that are extraureteral, and still more surprising is the large percentage (30 per cent., Baetjer) of ureteral stone which the *x*-ray entirely misses. By means of the wax-tipped and bismuth bougie, in conjunction with the *x*-ray and stereoscope, we can discern with almost certainty the presence or absence of ureteral stone. Every urologist of experience can cite examples confirming this experience.

In conclusion, I would like to submit a résumé of the results obtained by the Genito-Urinary Department of the Mercy Hospital within the last few years, as a result of the application of these methods.

The number of cases studied was 113. Of this number 41 were kidney or ureteral stones; there were 21 cases of renal tuberculosis; 5 of hydronephrosis; 16 of pyonephrosis; two of hypernephroma; one of polycystic kidneys; 4 of essential hematuria; 3 of perinephritic abscess; one of ruptured kidney, and 11 miscellaneous conditions of the kidneys. Of this total number, 48 were operated upon, the writer officiating in 33, the remaining 15 being operated upon by the various surgeons of this same hospital. The correct diagnosis was made in every case coming to operation. There were two operative deaths, one from shock and the other from pulmonary embolism three weeks after operation. Of the cases operated upon by the various general surgeons after previous study by the urologist, there was no mortality. In the same period of time, there were operated upon a number of kidney cases by most of these same surgeons, which were not subjected to preliminary study. The mortality rate and incorrect diagnoses were extremely high. This feature clinches the point I wish mostly to emphasize, viz., if your cases are not studied carefully before operation your mortality rate will be high regardless of the skill of the operators; and the percentage of erroneous diagnoses, often resulting in unnecessary operations, will be even higher.

Professional Building.

Mortality of the Portuguese Allied Army.—The Portuguese sent in all 45,000 men to fight with the French. Of this number 2,000 perished and 6,400 were wounded. Those who died of disease numbered 300. This figure included but 5 cases of typhoid fever and there was not a single death from smallpox.—*La Presse Médicale.*

Post-mortem Specimen of a Radical Mastoid Operation Performed Six Months before Death.—E. D. Davis reports the case of a comedian, who had suffered for some years from pulmonary tuberculosis. During sanatorium treatment he developed mastoiditis and facial paralysis, following chronic otorrhea. At the time of the radical mastoid operation he was suffering from advanced laryngeal and pulmonary tuberculosis. The mastoid process was extensively involved, and in removing the focus of disease a large area of the dura mater of the middle fossa was exposed. The postaural wound healed by first intention, and the patient left the hospital after ten days with the symptoms relieved and health improved. When seen about six months before death, the mastoid cavity was satisfactory. The post mortem showed extensive laryngeal, pulmonary, and intestinal tuberculosis. The dura mater in the middle fossa was thickened and the exposed area was covered by tuberculous granulation tissue. The petrous bone below the dura and surrounding the opening made at the operation was necrosed. The brain was normal and the meninges, except those in the area of operation, were healthy.—Proceedings of the Royal Society of Medicine.

THE EVOLUTION OF TYPHOID SPONDYLITIS.

THE evolution of typhoid spondylitis is generally slow, and being as yet insufficiently known it cannot be divided into types or forms, but it is probable that besides the varieties having a distinct symptomatology there are others whose clinical signs are more or less vague. Its progress is decidedly capricious; sometimes after an acute phase of short duration the spondylitis continues its evolution insidiously for a considerable period of time without provoking the slightest febrile reaction, making itself manifest merely by dull pain. At other times its onset is at first symptomatically silent, and then a phase of highly acute phenomena suddenly develops. The process usually progresses in phases of alternating recrudescence and amelioration and it may also remain quiescent for months only to reappear. The total duration of the evolution of typhoid spondylitis is very uncertain; Lance maintains that it varies from one month to two years or more; it usually is between three months to one year.

It would seem logical to admit that there is a close relationship between the intensity of the vertebral inflammation and the duration of the spondylitis; and unquestionably this is often so, but it will be noted that the most acute cases are not necessarily the longest. Although few cases have been met with in children, it would seem that in them the evolution of the process is more rapid than in the adult, this being probably due to the fact that in childhood the osseous system being in full activity defends itself better against the infection. But the principal factor which singularly shortens the duration of this complication is early treatment, therefore it is essential to detect the spondylitis early in its development.

The prognosis, so far as life is concerned, is good. It is also questionable whether typhoid spondylitis ever develops into a suppurating process. That this might occur may seem likely when other bone lesions of typhoid are considered, but Guyot's case was not one of typhoid spondylitis, and for that matter he published it under the title of vertebral osteomyelitis of typhoid form. In Morian's case the process was a staphylococcic vertebral osteomyelitis, while in Painter's case it would seem more probable that the process was a coxofemoral arthritis, because an ankylosis in flexion of the hip-joint occurred shortly after. In Rock-Carling's case, the patient had undergone a laparotomy a few months before, and a pelvic suppurative process preceded the appearance of the spondylitis. There are only two other recorded cases, by Weigel and Myers respectively, which ended in suppuration, but it is probable that the purulent epiduritis with the bacillus of typhoid reported by Raymond and Sicard was, in reality, a suppurating typhoid spondylitis.

Nearly always typhoid spondylitis ends in resolution. In the milder forms *restitutio ad integrum* may be complete, but usually a more or less pronounced stiffness of the spine remains. When not very extensive, the stiffness may not be noticed on account of its localization in a part of the spine which is less mobile, so that it can be detected only upon close examination. In other instances a very considerable stiffness results, a persistent rigidity easily explained by the disappearance of the intervertebral discs and ossification of the perivertebral ligaments as demonstrated by radioscopy. In reality, it is a true synostosis between two or several vetebræ. All things considered, spondylitis is a relatively mild complication of typhoid and has the same benign prognosis as the other osseous complications arising during convalescence from this disease. However, it may well be questioned whether or not a typhoid spondylitis which is supposed to be cured is capable of becoming active again after a long period of silence, or at least of playing some part in the etiology of the chronic spondylitis the study of which offers so many points still to be explained.

CONCERNING TUBERCULOSIS.

THE prevalence of tuberculosis in Europe has increased very considerably as a consequence of the war, of which it is one of the saddest aftermaths. In Great Britain the increase of mortality from the disease is said to reach 12 per cent. In France the increase has been no doubt even greater, and on the Continent generally, as was only to be expected, the incidence of and mortality from tuberculosis have been augmented. Before the war steps had been taken to arrange for the carrying on of a much more vigorous campaign against the malady in America and Great Britain than had been waged formerly, but in the latter country the war had the effect of almost completely stopping these plans. At the British Tuberculosis Congress, held in 1913, it was thought and said that a crusade conducted on certain lines which had been mapped out would result, if not in the extinction of tuberculosis, at least in a most satisfactory curtailment of its powers for evil. It was thought that knowledge of the disease was such that it only required to be put into practice thoroughly to achieve the end desired. The war, however, appears to have shown that these hopes were premature.

The experience of France demonstrated the fact that a large proportion of its population suffered from latent tuberculosis, which the stress and strain on the nervous system and physical powers brought about by the war rendered active. According to Col. Rist not fewer than 80,000 men were discharged from the French army because of tuberculosis. It is stated that at the beginning of the war, owing to the urgent need for men, the examinations were hasty, and many tuberculous subjects were passed into the army. The result was inevitably widespread infection to such an extent that the French Government in 1917 accepted the American offer of help through the Rockefeller Institute. The final outcome of the efforts of the American physicians and nurses will not be evident for some time to come, but up to the present time the work has afforded grounds for hope.

It is recognized in Great Britain that while in many respects its tuberculosis specialists have been pioneers in treatment, at the same time they have been too conservative, too narrow in their views, in fact, and afraid to launch out in the same way and to the same degree as the Americans. For example, Professor William C. White of Pittsburgh, in an address delivered before the conference of the British Association for the Prevention of Tuberculosis, spoke of the work which has been and is being done by the tuberculosis nurse in America. He estimated at 60 per cent. the nurse's share of all the work done against tuberculosis in America. Sir Arthur Stanley, chairman of the Joint War Committee of the British Red Cross Society and the Order of St. John, speaking at the same meeting, announced that the Red Cross would find funds for anti-tuberculosis work, and in addition a very large number of women would gladly give their services to the same cause.

Dr. Christopher Addison, the Minister of Health, who gave the opening address at the Tuberculosis Conference, laid most insistence on adequate, sanitary and comfortable houses as a means of combating tuberculosis. The sanatorium did not appear to be regarded with so much favor as formerly, although, as one speaker remarked, it was not the fault of the sanatorium, but was due to the fact it was not usually employed properly. The consensus of opinion expressed by the speakers was that in order to fight tuberculosis successfully coordination is required, and to obtain such coordinated effort the masses must be educated in public health matters. It may be noted that at the conference it was acknowledged that American organization for dealing with tuberculosis was the most effective.

THE DANGERS OF HOME CANNING.

DURING the past few years there have been an increasing number of instances of food poisoning due to the ingestion of *B. botulinus* toxin in home-canned foods. The frequency of the report of these attacks has been such that not a few individuals have become suspicious of all home-canned food. The situation is a serious one, for a satisfactory method of preserving food, one readily applicable to home-canning, is necessary if large quantities of foodstuffs are to be saved from spoiling each year. The subject has been investigated recently (*Archives Int. Med.*, 1919, xxiv, 581) by E. C. Dickson, G. S. Burke, and E. S. Ward. These authors have shown that the spores of the *B. botulinus* when mixed with food material may survive heating for three hours in boiling water. A further investigation of methods of canning in which lemon juice or sugar was added to the food, either with or without the addition of a brine, showed that the only method which was efficient in destroying these spores was one in which salt and a fairly high concentration of lemon juice were employed. This method is one described by W. V. Cruess in Circular No. 158 of the University of California Agricultural Experimental Station. Lemon juice is added in the proportion of from five to seven ounces to each gallon of mixture. In all of the other methods tested, foods and fruits which had been inoculated with a culture of *B. botulinus* showed the presence of viable spores of that organism, and tests upon guinea pigs showed that the foods contained the characteristic toxin. It may be said that the amount of toxin production was apparently less when a fairly large amount of sugar had been added to the food. The authors are of the opinion that the same conclusions can be reached from a consideration of the commercial canning processes, but that the system of repeated inspection which is followed results in quite adequate protection of the consumer.

It is apparent that the cases of botulism have been few because food is comparatively infrequently contaminated with the *B. botulinus* and also because commercially canned foods are subject to careful and repeated inspection. It must be remembered also that the toxin developed by this organism is destroyed by heating so that infected foods that are thoroughly cooked before serving may be eaten with impunity. So it is necessary to emphasize the importance of cooking canned food before it is eaten. It is difficult to judge whether this form of poisoning is becoming more frequent or whether it is being recognized more frequently. Probably both factors are of importance, for more canning is being done at home than ever before and it is to be expected that some of the methods followed are imperfect in themselves or that the technique used is not that directed. At any rate the matter is one of great importance to the whole country and the facts of such investigations as these should receive wide circulation.

A NEW DEPARTURE IN MEDICAL JOURNALISM.

WITH October, 1919, began a new medical periodical issued from Paris, a monthly of which each number will be devoted to the latest developments of one particular branch of medicine. The title is *La Médecine*. Original articles, abstracts, book reviews

—in fact, the entire contents of each number are devoted to the special province chosen for the month. The October number is devoted to General Surgery. Fifteen brief, original articles covering the most prominent aspects of modern surgery are contributed by as many distinguished French surgeons with brief summaries in the English and Spanish languages. As several of the articles deal with surgery of the urinary organs it is probable that it is the intention of the editors to include this branch under general surgery. The November number deals with Dermatology primarily and incidentally with Syphilis. No program is announced, which seems wise because no one can foresee the trend of medical thought very far ahead, and greater liberty of choice becomes possible. Among the patrons of the enterprise we note the names of Bergonié and d'Arsonval—both eminent medical physicists, Richet the physiologist, Widal the internist, Calmette the serologist, while America is represented by Persillier-Lachapelle of Montreal. The editorial staff consists of thirteen well-known clinicians, one of whom will presumably be responsible for one monthly number. The surgical number was edited by Mathieu and the dermatological number by Gougerot. Each editor contributes a general article on the present status of his specialty.

Perforation of Duodenal Ulcer.

From what is known at present regarding perforation of ulcers of the duodenum this condition should be suspected when a patient complains of a sudden and severe abdominal pain located in the epigastric area or towards the right side of the abdomen, accompanied by great tenderness on pressure over this area, and above all by reflex contraction of the abdominal walls—a diagnostic sign of the highest importance. In a subject who offers a maximum of pain in the right iliac fossa or over the region of the appendix, one should be distrustful of the suddenness of the onset, the nature of the pain, and the intensity of the symptoms at the beginning of the paroxysm, and only after a very careful history of the case, and a minute examination of the signs should the diagnosis of appendicitis be accepted. With the above symptomatology an immediate operation should be resorted to. It is idle to wait to see if it confirms the diagnosis by becoming aggravated, as valuable time is lost. A median incision should be made above the umbilicus, even if a previous incision has been made over the iliac fossa, revealing the fact that the origin of the symptoms is not the appendix. Whenever possible an excision of the ulcer, followed by duodenoplasty should be carried out, if a somewhat long operation is not contraindicated; otherwise the perforation and ulcer should be brought under a row of catgut sutures following a line perpendicular to the axis of the duodenum. If by proper closure of the perforation too great a reduction in the size of the duodenal lumen is to be feared, and if the patient's condition will permit, a complementary gastroenterostomy may be done at the same time. Intraabdominal irrigation is indicated only in cases of extensive peritonitis, in connection with which there is much food detritus contained in the folds of intestine.

News of the Week.

Examinations for Appointment in the Medical Corps of the Regular Army.—The Surgeon General of the Army announces that preliminary examinations of all eligible applicants for appointment in the Medical Corps, U. S. Army (regular) will be held on March 15, 1920, at various points throughout the United States, in the Philippine Islands, Hawaiian Islands, Panama Canal Zone, and Porto Rico, and in France, Germany, and Siberia, of applicants in the military service. The essential requirements for eligibility to take the examination are that the applicant shall be a citizen of the United States, of good moral character and habits, between twenty-two and thirty-two years of age, a graduate of a medical school legally authorized to confer the degree of Doctor of Medicine, and shall have had at least one year's post-graduate hospital interneship. The requirement that an applicant for appointment in the Regular Medical Corps shall have served at least a year's post-graduate hospital interneship, is waived in the cases of those applicants who have satisfactorily served as commissioned officers for a period of at least one year during the World War. While the present maximum age limit for appointment in the permanent Medical Corps is fixed at thirty-two years, it is believed probable that by prospective legislation that limit may be modified somewhat in the cases of those applicants who have had military service during the World War, and who are beyond the present age limit. Any such person may, therefore, submit application regardless of his present age, in order that he may be given opportunity for examination, should the suggested change be made prior to March 15, 1920. Applications should be in letter form, addressed directly to the Surgeon General, United States Army, Washington, D. C., and should have embodied therein the following data in the order indicated: (*a*) Name in full (initials not acceptable). (*b*) Date of birth. (*c*) Place of birth. (*d*) Permanent home address. (*e*) Medical school or schools from which graduated, with dates. (*f*) Professional experience. (*g*) If an officer who has served during the emergency, complete statement of military service, setting forth (1) the organizations in which served and inclusive dates, (2) present organization, if still in the service, (3) grade in which originally appointed, (4) present grade if still in the service, (5) date, place of discharge, and rank at time of discharge if no longer in the service. (*h*) Statement of any service as a contract surgeon, in the Medical Reserve Corps, in the Medical Section, Officers' Reserve Corps, or in the Medical Service in Volunteers. (*i*) In cases of alien birth, (1) documentary evidence of naturalization, (2) if naturalized through parent, documentary evidence of father's naturalization and sworn statements from two reputable United States citizens establishing relationship between candidate and his father. At the present time there are, approximately, seven hundred and thirty vacancies in the Medical Corps.

Woman Physician Decorated.—Dr. Caroline Finley, head of a Suffrage overseas hospital, was decorated and vested with membership in the Order of the British Empire, by the Prince of Wales on the deck of the *Renown*, November 22, in recogni-

tion of services rendered at Metz, during the influenza epidemic, to British soldiers just released from German prison camps.

Annual Report of Rockefeller Foundation.—According to the report of the Secretary, William R. Embree, the Rockefeller Foundation spent, during the year 1918, $1,255,990 for public health work, including the hookworm, malaria, and yellow fever campaigns, the anti-tuberculosis work in France, the after-care of infantile paralysis cases, studies and demonstrations in mental hygiene, the School of Hygiene and Public Health, Johns Hopkins University, the study of dispensaries, the National Organization of Public Health and Nursing. Disbursements for medical education and research totaled $2,419,866.

Asks Hospitals for War Risk Men.—Surgeon General Blue of the Public Health Service has asked Congress for the sum of $85,000,000 with which to build and equip hospitals with 30,000 beds for the care of war risk insurance patients. These accommodations, he says, will be needed by July 1, 1921.

Typhus Serum.—According to press notices Dr. Benito Sanches of Mexico City has discovered a serum that cures typhus fever within forty-eight hours.

Nursing Rates Raised.—The twenty-one organizations representing the graduate nurses of Greater New York are contemplating an advance in general nursing rates. In several cases a new schedule is already in operation. The rate for general nursing has been raised from five to six dollars per twelve-hour day, with seven dollars for twenty-four hours, including the usual requirements of two hours for recreation and six hours for sleep in the longer period. In mental and contagious cases the charge is seven dollars per day. Rates for private or special hospital cases are not included in this schedule.

Influenza Mortality in Switzerland.—The Swiss Sanitary Department reported recently that 22,689 persons died during the influenza epidemic.

New Hospital for Jamaica, L. I.—It is announced that the trustees of Jamaica Hospital will erect a new stone hospital to accommodate 125 patients. The building will cost $250,000.

The Park Hospital, having been used by the Navy Department for more than a year for the care of sick and wounded sailors and marines, is again prepared to admit free cases to the male, female, and children's wards.

Dr. Thomas Wood Hastings, late Major, M.R.C., has resumed his practice at 777 Madison Avenue.

Dr. Henry Wirt Jackson, formerly Major, M.R.C., has established an office at 777 Madison Avenue, where he is associated with Dr. Thomas Wood Hastings.

Dr. Max Kahn has resigned from the Brooklyn Diagnostic Institute.

Medical Society Elections.—The ELEVENTH DISTRICT MEDICAL SOCIETY held its annual meeting at Douglas, Ga., November 29. Dr. R. C. Woodward of Adel was elected president for the coming year, and Dr. J. W. Simmons of Brunswick was elected secretary.

Obituary Notes.—Dr. JAMES DUDLEY MORGAN, Asst. Surgeon, U. S. Navy, Washington, D. C., died at his summer home at Chevy Chase, Md., November 21, at the age of 57. Dr. Morgan was graduated from George Washington Medical Department in 1885. He was demonstrator of anatomy in this institution from 1888 to 1889, lecturer on differential diagnosis from 1897 to 1898, and associate and clinical professor of medicine from 1910 to 1917. He was connected with the Garfield Hospital and the Emergency Hospital, and was a member of the American Climatological Association, and of the Medical Society of the District of Columbia.

Dr. JOHN HEY WILLIAMS died at his home in Asheville, N. C., November 14. Dr. Williams was born in Kentucky September 7, 1842. He was graduated from the College of Physicians and Surgeons, Keokuk, Iowa, in 1863.

Dr. James A. Struble, of Passaic, N. J., died December 3, at the Home for Disabled Soldiers, at Kearney, N. J., in his 77th year. Dr. Struble fought with the New York Mounted Rifles in the Civil War.

Dr. Adolph Hoerr, of Mamaroneck, N. Y., died of arteriosclerosis, November 12, at the age of 50. Dr. Hoerr was graduated from the New York University Medical College in 1896.

Dr. E. REID RUSSELL of Asheville, N. C., died November 28, from blood poisoning, at the age of 49. He was graduated from the University of Maryland School of Medicine in the class of 1895. His practice was limited to otolaryngology.

Dr. E. H. SIMS died at his home in Columbus, Ga., November 27. Dr. Sims, who was 60 years of age, was graduated from Emory University School of Medicine in 1883.

Dr. GEORGE E. ADAMS of Worcester, Mass., dropped dead while attending a patient, November 29. Dr. Adams was 67 years of age. He was graduated, in 1880, from the Medical School of Harvard University.

Dr. SAMUEL AUGUSTUS WOOD died at his home, Elmhurst, L. I., December 12. He was graduated from the College of Physicians and Surgeons, New York, in 1879.

Dr. D. B. HUNT of Otego, N. Y., died December 6. He was graduated from the New York Homeopathic Medical College in 1873.

Dr. JAMES HAMILTON CUMMINS of Newark, N. J., died December 4. He was graduated from Bellevue Hospital Medical College in 1890.

Dr. LOUIS A. SPAETH of Wyncote, Pa., died in a hospital in Abington, Pa., after a year's illness, at the age of 57. He was a veteran of the Spanish-American War and of the World War.

Dr. CHARLES W. PILLSBURY of Saco, Me., died December 3, in his 69th year. He was graduated from Dartmouth Medical School in 1881.

Dr. CHARLES H. COOK of Natick, Mass., died December 3, after a week's illness, at the age of 74. Dr. Cook was graduated from Bellevue Hospital Medical College in 1875, and had practised in Natick since that time. He was a member of the State Board of Registration in Medicine at the time of his death. He was president of the Federation of Medical Examining Boards of the United States in 1915 and 1916.

Dr. E. G. DEARBORN of Antrim, N. H., died at Memorial Hospital, Nashua, N. H., where he was under treatment, December 2, at the age of 40. Dr. Dearborn was graduated from Harvard Medical School in 1904.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, November 28, 1919.

Centenary of Charing Cross Hospital—The Centenary of Charing Cross Hospital and Medical School has just been kept. Charing Cross Terminus is one of the "gates of the world" and the hospital building is near by. The present building is not so very old judged by several other buildings of the kind in London, as it was designed in 1831 by Decimus Burton. Huxley and David Livingstone the great African explorer received their medical education at Charing Cross Medical School. The centenary gave added interest to the distribution of prizes to the successful students. Sir Auckland Geddes in congratulating the prize winners said that those who did not figure among them might draw comfort from the fact that the biggest prizes of life had still to be fought for. Those who like himself had participated in the National Service movement, enjoyed exceptional opportunities for getting to know the mental habits of the medical profession. The first lesson they learned was that the medical profession was extraordinarily unequal not only in its technical knowledge but in its public spirit. It achieved a glorious record in the war, doing magnificent work, but perhaps few realized that that fine record was won for the profession as a whole by a minority of its members; because there were a number of people, now sharing in the glory won, who did absolutely nothing to help it. In all professions there was a certain sprinkling of self-centered persons, but it had seemed to Mr. Meagues and himself that the medical profession possessed a much larger share of those than it ought to have. In some schools the whole outlook was so limited that the teaching given was little more than technical instruction. That was why so many men failed to rise to the height of the occasion when a great occasion came to them. In the medical class room a mental sharpening, a development of the power of the mind was going on, altogether apart from the mere stuffing of it with information. Students had themselves the power to turn the instruction given into matter for their mental education. Sir Auckland Geddes pointed out that teachers could act only as finger posts to indicate that there was a path in this or that direction to be explored. The determination to explore and the exploration itself must come from the students. It was always true that after their school life people would educate themselves. Doctors had a reputation for appreciating the need of social service because of the action of the leaders of the profession. The more they went through life the more they would want to feel that they were doing something to make the whole body of the profession equal to the reputation which the best men in it had gained for it. If they did that they would serve their day and generation well.

It may be mentioned that Charing Cross Medical School is one of the few in London and indeed in Great Britain which admit men and women to education on exactly the same terms. Miss S. A. Cooper took eight of the chief prizes and the remarks of Sir James Galloway that the experiment of medical coeducation was a complete success appear to be quite justified.

Industrial Colonies for Consumptives.—For some time there has been more than an uneasy suspicion that sanatoriums for the tuberculous have not equalled expectations. This feeling of dissatisfaction was voiced by more than one speaker at the Tuberculous Conference held recently in London. According to Sir George Newman, Chief Medical Officer of the Ministry of Health, the results of sanatorium treatment in Great Britain have been somewhat disappointing. In his opinion all sanatoria should be connected directly or indirectly with colony treatment. Also with regard to hospital provision for advanced cases Sir George holds some advanced views. He is of the opinion that such hospitals should not take the form of "homes for the dying" as he thinks that "advanced" cases are not always hopeless or dying. As for tuberculosis colonies there exists a considerable degree of unanimity of opinion that these are useful and when carried on in a common-sense way are necessary. There are six tuberculosis colonies in Great Britain of which that at Papworth is the only one which is really an industrial colony.

At the Royal Institute of Public Health on Nov. 20, Dr. P. C. Varrier Jones, the Hon. Medical Officer of the Papworth Colony, gave an address on industrial colonies for consumptives in general and on Papworth in particular. Papworth colony possesses the distinction of being the first village center wholly devoted to the care of the tuberculous. The old idea of a colony, which still prevails to a large extent, was merely a place at which sanatorium treatment was prolonged. The original colony treatment did not differ much from nor was it much better than sanatorium treatment. The sole notion of treating the tuberculous not many years ago, and this notion is not yet dead, was to provide the patient with what was termed a light occupation in the open air. The light occupation usually took the form of gardening or sometimes of agricultural labor. Now, as Dr. Jones pointed out, gardening as a rule is harder than a skilled indoor occupation, while agricultural labor is infinitely harder. In fact agricultural labor, as is being found out, is a highly skilled form of work of an extremely laborious nature. Therefore, the unskilled consumptive gardener and the unskilled consumptive agricultural laborer are quite at the bottom of the list so far as earning capcity is concerned. These men can hardly keep their own bodies and souls together by the work and of course are altogether unable to maintain the wife and family, which so many of them have. The entire question is largely an economic one. Dr. Jones insists that too much emphasis is laid on the virtues of the open air and that there is little sound reason for condemning skilled factory work. The modern factory is well ventilated and the work is not hard, and it is better to be able to earn decent wages and to know that one is able to support the wife and family and to provide oneself with good nourishing food than to earn a bare subsistence at an unskilled out-of-door job. But, of course, the con-

sumptive cannot work on equal terms with normal men in an ordinary factory. To begin with, there is usually a prejudice against him, as, unfortunately, the consumptive is a marked man. Moreover, in a modern factory in which machinery is king and every man has his appointed task and in which punctuality is more than a virtue, it is a necessity, there is obviously no place for a man who may have to take an hour or so or a day or two off now and then. Hence the need for the industrial colony and village center—a community of those suffering from tuberculosis, in which hygienic and economic factors have been so arranged that the work is well adapted for such patients. They are guaranteed against excessive fatigue, their work is purposeful but not stereotyped or monotonous. And they have the advantage of living in the country amid beautiful and healthful surroundings, and if married, with children, can live in a separate house with wife and family.

The description sounds ideal and Papworth industrial colony has demonstrated that such a system can be carried out with, at least, satisfactory results.

The Housing Problem in England.—With regard to the provision of houses the Ministry of Health appears to be marking time. As a matter of fact Dr. Addison and his colleagues are in a very awkward situation. They are willing and anxious to have houses built, but labor is scarce and dear, the price of material is high, and the result is that the cost of a very modest house is simply appalling. The Government is about to grant a subsidy for each completed house, but with this aid the ordinary workingman cannot afford to pay the rent that the owners must ask to get a fair interest on money expended. It is said that a house of any sort, that is adequate, sanitary and comfortable, cannot be erected for less than £800. At five per cent. the rent will reach the sum of £40; subtract from that the interest on the subsidy, £7 10s., and the rent will come to £32 10s., a sum considerably beyond the means of the British workman. It seems to be almost an impasse, although it is to be hoped that a way out will be found. It is conceded on all hands that decent houses are needed in every part of the country, town and rural district alike; it is also conceded that much of the disease which prevails is due to inadequate unsanitary housing, and the news that the first steps to be taken in the direction of preventing disease were to build at once an immense number of good houses, was hailed as a master stroke of wisdom and policy. The Ministry of Health came in with the avowed object of demonstrating the truth of the saying, *salus populi suprema lex*, and it is hard indeed that the fates have not been more propitious.

The State in Relation to Chronic Disease.—On November 13 a Chadwick Public Lecture was given at the rooms of the Medical Society of London by Dr. R. O. Moon. The feature of the lecture was the warning uttered against the danger of the specialism which isolates departments of knowledge. According to the lecturer, too static a view is taken of chronic diseases. They overlap and flow into one another and their apparent definiteness, fostered by nomenclature, is fallacious. The first duty of the State in connection with disease is prevention. The primary duties of the State with regard to prevention are: (1) To secure a pure water supply; (2) to supply unadulterated food and good milk; (3) removal of dust and smoke; (4) house and town planning; (5) restriction of the consumption of alcohol. Dr. Moon said the chronic diseases at present dealt with by the State were insanity and tuberculosis. There was a great need for hospitals or special houses for borderland cases. The exaggerated idea of the infectivity of "Consumption" had to be combated. Post-sanatorium treatment for the tuberculous, he maintained, should be amply provided.

He laid these on the importance of civic efficiency to the Nation and pointed out ways of dealing with inefficiency resulting from circulatory disorders and epilepsy. Similar work to that which was being done by employment bureaus for disabled soldiers should be applied to all citizens suffering from chronic diseases. Doctors recommended "light work" but there was difficulty in defining it, and medical men should become familiar with the amount of work involved in various forms of industrial and agricultural occupations.

Supply of Medical Men in Great Britain.—Presiding on November 25, at the opening of the 110th session of the General Council of Medical Education in Great Britain, Sir Donald MacAllister, the president of the Council, said there was no doubt that in a few years the ranks of the medical profession would be more than replenished. In some minds the expected influx was giving cause for anxiety lest the new practitioners might not all be able to find employment when they reached the register. But it must be remembered that, on the one hand, the wastage of war had been great, and on the other, the opening for skilled men and women would be multiplied by the increased activities of the new authority concerned with the conservation of health and physical welfare of the people.

Anthrax and Shaving Brushes.—Dr. W. J. Howarth, the Medical Officer of Health for the City of London, has been inquiring into anthrax in connection with the use of shaving brushes. Several cases have been reported recently. As the result of investigations by the City Bacteriologist, Professor Andrewes of St. Bartholomew's Hospital, a consignment of brushes from Japan has been reported as infected with anthrax. In 1917, Dr. F. J. H. Coutts of the English Local Government Board made an investigation into the matter and reported thereon. He concluded that the principal source of infection was horsehair consigned to a brush manufacturer as "goat hair," and consequently not deemed to require disinfection under the Horsehair Regulations. Dr. Coutts pointed out that the methods of disinfecting horsehair from the Far East were unsatisfactory, and the Anthrax Disinfection Subcommittee is now investigating in order to find out whether the successful measures employed in the disinfection of wool could not be applied equally well to the disinfection of horsehair.

THE TREATMENT OF INFLUENZA.

To the Editor of the Medical Record:

Sir:—After an inquiry among many members at Council and other meetings of the American Therapeutic Society held recently, I regret that owing to the fact that the reporter of that Society failed before sending them to you, as is usually done, to submit the stenographic notes to the various members who took part in discussions of the papers read at the meeting last June, erroneous statements have appeared in the report of the annual meeting of that Society. The statement, for instance, in the Medical Record, October 25, p. 710, that I had been a pupil of Pasteur and the excellent results obtained without medication in influenza, applied to my friend Lieut.-Col., then Major, Ernest Laplace, who, when in charge of the medical service at Fortress Monroe, I am told, had the lowest mortality in the army, 1.3 per cent. Emergency Hospital No. 2, with which I was connected, was only mentioned as a basis of comparison, to show that with the measures generally advocated, our mortality was considerably greater, though not high, in view of the fact that probably the worst pneumonia cases, often moribund, were sent to us.

As it is impossible in the summary published to tell where Dr. Laplace's statements end and where mine begin, I must crave your indulgence for a few lines of explanation of the underlying causes of Dr. Laplace's success. He insured rest and warmth from the start. The paramount importance of rest in the recumbent position is generally understood, but the physiological importance of warmth is not. It is true, as your abstract states, that I anticipated Abderhalden several years in recognizing our digestive ferments, notably trypsin, as our active defensive agents. Abderhalden called them "defensive ferments"; I had termed them, along with other participants in the defensive process "autoantitoxin," as those who have read my writings well know. Now, as biochemists have shown, the activity of a ferment depends, up to a certain limit, upon the heat energy to which it is subjected. Thus, purified trypsin begins to lose its power at about 104° F. Up to this limit its action, that of decomposing various bacteria much as it does the nitrogenous constituents of foods, is effective. When, therefore, the normal body temperature is exceeded, the excess up to 104° F. constitutes "fever"—in truth a protective function having for its purpose the destructive digestion of the pathogenic organism and its toxins. When Dr. Laplace, besides a preliminary purge, and the free use of water to facilitate elimination, saw to it that his men were kept warm, he aided Nature in fighting the pathogenic bacteria and thus saved more lives than random medication could ever have done. Hyperpyrexia and its dangers are, of course, important features of the process, but its discussion would take us too far afield in the present connection.

Charles E. de M. Sajous.

Philadelphia.

Dangers of Strophanthine.—Of late numerous accidents have been attributed to too high dosage of this substance, which fact has led to a demand for revision of dose. Richaud would make the maximum dose not greater than one-tenth of a milligram.—*Bulletin général de thérapeutique.*

3. Low Arterial Tension, Etc. George Van Ness Dearborn.
4. The Scarlet Fever Wave in 1919. Stanley H. Osborn.

3. Low Arterial Tension.—George Van Ness Dearborn states that the complete independence of pulse pressure from blood pressure is indicated by very numerous hemobarograms made by his "continuous" method, varying in length from five to a hundred and twenty minutes, but mostly about thirty minutes, and on ages from five years to seventy-three, both sexes, in numerous degrees of vigor and of health (especially of mental health and disease). Children of health and sturdiness regularly have low levels of tension ("hyposphyxia") with diastolics of 40 mm. Hg. and lower, but high contrast between the systolic and the diastolic averages: normal and infantile pulse pressure. Old persons, on the other hand, with the usual (but usually *unnecessary*) degree of arteriosclerosis, frequently have high arterial tensions from moment to moment, but sometimes they have low pressures, because their diastolic tension is apt to be high, and their hearts *relatively* inefficient. His records show no correspondence as such whatever between blood-pressure and pulse-pressure, and vasomotor control being far too various and complex to make physiological any such direct relation. Moreover, they represent very different functions in the individual. This irrelation apparently accords especially with the duality of arterio-tensional control. The ever-varying systolic tension represents especially the ever-changing output of the left heart, which latter is very quickly variable in size (Gesell) as well as in the frequency of its contractions. The diastolic tension is more dependent on autonomic vasomotion, direct and reciprocal. Thus the systolic variations are more mental and the diastolic more somatic and "biologic." Divergence and convergence of the plotted curves representing respectively the systolic and the diastolic tensions are under investigation in the writer's clinical workshop. Cases are cited and hemobarograms given. Low general pressure (without regard to pulse-pressure), in the writer's opinion, is a topic in pressing need of study more systematic and deliberate than any one has apparently given it. There are a good many over-worried or over-studious young persons of each sex, but more females, whose systolic tension ranges in the nineties, and diastolic in the sixties, fifties, and even forties for short periods; people without perceptible myocardial weakness or valvular leaks, and capable of a large amount of work—some of them college athletes. The writer emphasizes that most of these hyposphyxiacs are somehow only *functionally* wrong:—they are not "obese," not "neurasthenic," not in the "pretubercular state," and not primarily dyspeptic. They do tend to be anemic, nervous, over-worried and *flabby-muscled.* Indeed, it is quite certain that part of the lowness of their "arterial" tension is in reality the lowness of the tension of the muscles on which the pressure of the sphygmomanometer-cuff partly, or mostly, rests. The real blood-pressure (as Brooks and Luckhardt showed) is far below the compensating pressure in the manometer, and in the cuff around the arm. Without speculating on the applied endocrinology which might cure these low tissue-tones and give them new motor "pep," the writer ventures to point out that these folk need effective re-education and fundamental regeneration above all else. The hill-farm, the ranch, "the good humored school of physical education," are among the re-educational agencies suggested.

1. The Causation and Treatment of Rickets.—Eric Pritchard. (See page 1028.)

3. The Treatment of Climacteric Hypertension.—Arthur H. Hopkins states that this type of hypertension has its onset at the menopause, or soon after, and that it occurs principally in apparently healthy women who are frequently overweight. These patients are active, highstrung, intense, excessively nervous, susceptible to worries and usually well supplied with them, according to their histories; again, they are extremely apprehensive, and if the physician inadvertently frightens, in his efforts to warn the patient of her condition, he has unconsciously added to his difficulties in the treatment. The not uncommon emotional instability of women at the menopause is, in these patients, excessive, and is readily reflected in a like instability in their blood pressure. The earliest manifestation is a marked rise in blood pressure, discovered not infrequently during a routine physical examination. Later, as the condition advances, the chief symptoms prompting the patient to consult medical advice are gastric and nervous disorders which are the most common. These symptoms constitute the gastric neuroses group, with fermentation and constipation in marked evidence. Nervousness and pains, chiefly in the limbs, are equally frequent; headache and cardiac embarrassment come next in frequency. The blood picture is strikingly normal, a secondary anemia being present only in cases in which there is some complication which could produce it. The kidney escapes damage, as is borne out by repeated urine analysis, functional tests, and forced proteid feeding. There is no evidence of peripheral fibrosis, at least for many years after the onset. The writer attributes the cause to the following facts, singly or collectively: 1. An alteration in the glands of internal secretion, possibly the withdrawal of curpus luteum functioning and its attendant influences upon the thyroid, adrenals, and pituitary. 2 Continued nervous strain caused by constant mental strain and worry, which adds still further to the emotional instability of the patient. 3. Constipation, which is present in varying degree in practically all cases. Overeating and multiple pregnancies are among the various other factors which have been suggested. In the treatment of climacteric hypertension the condition is divided into three stages: 1. In which high blood pressure and nervousness are the chief symptoms. 2. In which the pressure is higher and remains more constant and in which the gastric neurosis, cardiac or pressure symptoms, as headache, vertigo, etc., make their appearance. 3. Which comes later in life, i. e., in the sixth or seventh decade, and represents what might be regarded as the early evidence of senility. The management of the first stage, aside from the hypertension, is directed along the lines of rest and exercise, diet, elimination, and the treatment of the nervousness. In most cases these measures will prove sufficient in controlling and preventing the rise of the hypertension in this early stage. The writer believes that the majority of high pressures in the first stage should be let alone, in so far as vasodilator drugs, frequent sweat baths, etc., are concerned. Sometimes such symptoms as headache, vertigo, or tinnitus may warrant the tightening of the general restrictions and the use of sweat baths. In the second stage somewhat more rigid rules for rest, exercise, diet, etc., may be required, according to the condition of the individual. When pressure symptoms threaten it is well to inaugurate sweat baths, either cabinet or steam, every other day, regulating the duration and frequency in accordance with the condition and the response of the patient. When the pressure remains high and symptoms persist, it may become necessary to reinforce the sweating with the nitrites. Venesection, with the withdrawal of from 250 c.c. to 350 c.c of blood a day for several days, is useful in some of the more severe and obstinate cases. For the cardiac weakness, digitalis may be indicated if rest and a moderate reduction in pressure have not offered relief. The gastric neurosis symptoms must of necessity be treated symptomatically. In the third stage the two dangers to be reckoned with are cerebral hemorrhage and cardiac decompensation. Drugs, as a rule, are not indicated, but rather a general supervision of the patient's rest and activities, guarding against mental or physical strain, overdoing, excitement, etc., and guiding the patient finally into the formation of habits conducive to a simple, quiet life.

11. The Course of the Blood Changes in a Case of Anaplastic Anemia.—O'Malley and Conrad apply the term aplastic or aregeneratory anemia to a well marked type of anemia due to increased blood formation. Clinically it is marked by anemia, a profound tendency to hemorrhage, and a rapidly fatal course. Despite the severity of the anemia there are none of the evidences of bone marrow regeneration, such as megaloblasts, normoblasts, anisocytes, and stippled or basophilic erythrocytes in the circulation. At necropsy the red marrow is found to be aplastic, showing an increase of fat and a diminution in megaloblasts and normoblasts. A case is reported in detail on account of the remarkable opportunity it afforded for observing the progressive changes in the blood during the disease. The diagnosis was based on anemia, the absence of abnormal red cells in the circulation, and the aplastic red marrow at necropsy. There was no evidence of increased hemolysis. The red cells were reduced to about 1,800,000. They were only temporarily increased by transfusions, and they continued in about their original numbers to the end. The platelets were practically absent. The color index was below 1, and dropped as the disease progressed. There was an actual reduction in all the leukocytic elements of the blood, more marked in those of myeloid origin. Those of myeloid origin were the only elements to show progressive diminution in numbers.

5. An Experimental Research into the Specificity of the Agglutinins Produced by Pfeiffer's Bacillus.—Fleming and Clemenger, in this preliminary report to the Medical Research Committee, report the results of their work undertaken with the object of ascertaining

whether different strains of *B. influenzae* of Pfeiffer were identical in their immunity reactions—a question of some importance in regard to the etiology of epidemic influenza. The bacteriological findings in the recent epidemic have cast doubts upon the etiological relationship of Pfeiffer's bacillus to the epidemic infection. Where the bacteriologist used a medium which specially favored its growth, the Pfeiffer bacillus was shown to be present in something like 90 per cent. of the cases. It was rarely present alone, however, but was usually associated with pneumococci or streptococci. The bacillus was more commonly present in cases complicated with bronchitis or pneumonia than in simple cases. The question at issue is whether Pfeiffer's bacillus is the primary infective agent, or whether it is a secondary invader along with other organisms—pneumococcus and streptococcus—which ordinarily cause inflammatory conditions in the respiratory tract. Arguments against its being the primary cause of influenza are: (1) It has been found impossible to induce an attack by spraying the throat or nose with a pure culture of Pfeiffer's bacillus. (2) Pfeiffer's bacillus was very commonly present in catarrhal conditions of the respiratory tract for some years before the recent epidemic, and especially was it common in chronic bronchitis. In favor of its being the primary cause is the relative constancy of its presence in people suffering from influenza. If all the strains of Pfeiffer's bacillus could be shown to give the same immunity reaction this would form evidence in favor of the spread of infection from one person to another. But if the immunity reactions were different it would then appear probable that the infective agent was of a different nature and that it excited a secondary invasion with Pfeiffer's bacillus, which possibly was leading a saprophytic existence in the respiratory tract of the individual. The immunity reaction which was chosen for observation was agglutination, as this was easily observed and capable of accurate measurement. After describing the technique of the agglutination tests and giving tabulated statements of their findings, the writers conclude that these results show clearly that the different strains of *B. Pfeiffer* are very different in their agglutination reactions, and as there was so much difference between them it seemed quite unprofitable to engage in a more extended series of tests. In most of the cases the agglutins formed are either quite specific to the particular strain injected, or they are very nearly so, and in every case but one agglutination was observed in a much higher dilution with the homologous strain than with any of the others. So far as our present knowledge of epidemic bacteria goes, the findings, agreeing as they do with those of Dr. Park of New York, are considered a strong indication that Pfeiffer's bacillus is not the primary cause of influenza, but that the primary infective agent awakens the activity of organisms which have been leading a more or less saprophytic existence in the respiratory tract. These results are also of importance in connection with the preparation of stock vaccines of Pfeiffer's bacillus. The results obtained during the last epidemic have shown that such a vaccine is valuable both for prophylactic and therapeutic purposes, and the experiments of Fleming and Clemenger indicate that such a stock vaccine should consist of a very large number of strains.

3. The Causation and Treatment of Rickets.—Eric Pritchard considers it open to question whether the time has not arrived for a reconsideration of the whole subject of rickets—its definition, its etiology, and its treatment. The definitions with which he is acquainted appear to confuse cause and effect. If the term is not confined to the bony changes, but covers also all the various forms of malnutrition which ultimately terminate in rickets, the name means little else than a generic one for ill health in infants and young children. The view which Pritchard develops is that practically all varieties of malnutrition occurring during infancy and early childhood tend to terminate in rickets provided they are sufficiently severe or long enough continued. They should not, however, be regarded as evidence of rickets unless they are actually accompanied by the typical changes in bone which are characteristic of the disease. Shortly stated, the theory which he propounds is that the essential and central feature of rickets is the want of calcification or mineralization of developing bone, and that this in turn is due to the existence of requirements for calcium, which for the time being are more urgent than those of developing bone. These urgent requirements are the necessity for neutralizing acid bodies in the blood; in other words, to neutralize or compensate an existing acidosis. His argument is that all chronic conditions of malnutrition, of whatever kind, or from whatsoever cause arising, finally terminate in an acidosis, and that all claims on alkaline bases arising in connection with the neutralization of this acidosis must be satisfied before those of developing bone are attended to. The treatment of rickets naturally resolves itself into prophylactic and remedial measures. Prophylaxis is concerned with the avoidance of those mal-hygienic conditions which favor the development of the various forms of malnutrition described as associated with a deficiency of lime in the food, defective absorption of lime, intestinal intoxication, defective action of the endocrine glands, and deleterious respiratory influences. Remedial treatment depends largely on the correct diagnosis of the cause of the acidosis, on the treatment of the acidosis itself, and on the management of the complications arising from the softening of bone and of the emergencies which are secondary to the acidosis.

5. Cancer Progaganda.—A. L. Benedict, after taking stock of what the medical profession knows about cancer in form available for lay propaganda, sums up his attitude on the subject. In spite of all that has been said, he would still favor a lay campaign against cancer if it were not for the fact that every suggestion, strictly prophylactic or involving the arrest of cancer, which can be made to the laity can be placed on the broad basis of conserving health and preventing disease and death without reference to this particular disease. On this broad basis, the evils of terrorism can be avoided, even if it is thought best to mention cancer as one of the possible dangers to be avoided or arrested. The good results of a campaign will be magnified at least ten times by extending the range of diseases covered. This increase will be possible with scarcely any additional labor or expense. There will be no loss of professional influence from exposure of ignorance and no interference with the institution of a definite campaign against cancer if, at any time, a point is reached at which the profession can come before the laity with practical, definite statements.

Semeiotic Value of Curettage in Malignancy of the Uterus.—Gonin refers to the discrepancies between clinical and microscopic finds in cancer and sarcoma of the uterus. He has recently seen instructive cases of each of these affections from the standpoint of diagnosis. The corpus was of course the seat. The author recalls four cases reported by Burckhardt in which

clinically the diagnosis was cancer of the corpus. Then the curette was used for diagnosis and in not a single case was there a diagnosis of malignancy. But the disease seemed to be progressive and he felt obliged to extirpate all four uteri. After this had been done the uteri were split and the cavum carefully studied. Malignancy was indeed present, but the masses of cancer cells were so situated that the curette had missed them —at the fundus or in the tubal angles. Semon relates the case of a woman with subserous myoma of the uterus, the size of a cherry and seated in the fundus. But the cervix was first dilated and the cavum explored with the finger to make certain of the absence of malignancy, for the woman was of the cancer age and the uterus was enlarged and retroflexed. The scrapings obtained by the curette pointed to malignancy. Hemorrhages from the uterus could hardly be explained by the presence of a subserous myoma and the possibility of a submucous companion was verified by digital examination, a tumor lying above the internal os. Nevertheless the author performed vaginal hysterectomy and then learned that patient had suffered from an adenocarcinoma of the corpus. The submucous fibroid had prevented a proper curettage. Gonin, after citing other cases of confusion, gives his own observations which were of the same type. One woman 4 years after the menopause began to have a leucorrhea and bloody discharge which did not strongly suggest cancer. A polyp was found projecting from the cervix which was extirpated and the curette was then introduced for diagnosis. The conclusions were not favorable for a diagnosis of cancer and operation was refused for a long time. Later owing to pain and hemorrhage the uterus was finally taken out when evidence of cancer was forthcoming. In the other patient the biopsy was negative for cancer but after removal of the uterus the presence of a sarcoma was established.

Hygiea.

Blood Sugar and Diabetes.—Lindblom starts with the fact that in a healthy man there is equilibrium between sugar production and sugar consumption. This equilibrium must be constantly controlled and regulated. When overproduction is threatened, the blood sugar content is instantly augmented because the kidneys possess a certain imperviousness to a certain concentration of blood sugar. This hyperglycemia is a signal for sugar producing and sugar consuming organs, and in certain cases for the nerve centers that production must be speeded down or combustion speeded up, in order that equilibrium comes about. In the diabetic the ability to secure this equilibrium is either depressed or lost altogether. The concentration of sugar in the blood is too high for the kidneys to bring about equilibrium; hence only through the action of the organs themselves or the nerve centers can it be brought about, as already stated, by underproduction or overcombustion. Hyperglycemia is to a certain extent a conservative process because it antagonizes the metabolic derangement of diabetes. But the organs concerned in sugar metabolism and the nerve centers lose their sensitiveness to hyperglycemia and can respond to the latter only when the concentration is increased. If this does not come about, the original metabolic derangement is progressively aggravated. With time also the kidney becomes less and less pervious to sugar excretion. Hence our conception of hyperglycemia must be inverted; for it is not in spite of it but because of it that the urine may become sugar-free. In the oatmeal treatment the sugar content of the blood is increased, and that abruptly. Hyperglycemia is, however, not an unmixed blessing and the patient does not really improve until it vanishes. The ability of the organs to react to sugar excess in the blood is still below par, so that the carbon-poor diet is still indicated.

Trial Breakfasts.—Frenkel-Tissot writes at great length on the subject of the most practicable trial breakfasts for pathological states of the gastroenteric tract. He discusses the following: Ewald-Boas, Leube-Riegel, Kemp and a trial supper which is used in Kuttner's service in the Rudolph Virchow Hospital, Berlin, where the author has served as assistant. The principal aim in diagnosis by trial meal is to assist in the differentiation of functional from organic disease. The meals used answer the purpose completely and no changes are necessary; but more precision is desirable in their employment. They are superior to reagents which are used to test the gastric functions. Diet may be based upon them and the patient has no repugnance toward them. The breakfasts or meals for testing comprise a variety of foods and hence may be used in succession in the same subject. The Ewald-Boas meal comprises only a roll and tea. The Leube-Riegel is much more elaborate and comprises meat broth, black bread, mashed potato and beefsteak. The Kemp meal comprises oatmeal gruel, bread, raw minced and cooked meat, cranberries, plums. These two supplement each other very well and the finds should be contrasted. The skins of the berries and plums are of value in computing the interval before the stomach becomes quite empty. The evening test meal consists only of rice and seedless raisins. In using this method of diagnosis the passage of food is of maximum importance. In severe retention the stomach is never entirely emptied and in such cases form a special group of organic lesions. Next in order are the stomachs which empty themselves slowly. If after 12 hours the stomach shows retention the latter is termed permanent. No less than 18 per cent of the material tested was of this kind. Here functional and reflex disorders are excluded and the patient is regarded as suffering from organic disease. A case is called one of slow evacuation when the stomach is not emptied before 7 hours. The minutiae of the report predominate greatly over the underlying principles and the author makes few generalizations and draws hardly any conclusions.

Gazette des Hôpitaux.

September 6, 1919.

The Humoral Reactions of Chronic Pulmonary Tuberculosis.—Prevost concludes that the humoral modifications of this affection represent an incomplete immunity—an effort at immunization, which differs considerably from the immunity in various other infections. The humoral state of a tuberculous subject who is already impregnated by the bacillus and its poisons is a special condition, one of instability comprising reactibility to vaccines which are slow and the so-called allergy which is rapid. One or the other will predominate at a given time and provoke the intermissions which are so often seen and which are closely associated with the evolution of the disease by serial exacerbations. By itself neither reaction has any absolute value, and in the clinic they must be grouped. Three reactions possess value under these circumstances. The first of these is the opsonic index which should be tested serially, and is of prognostic value, but technically is very complex. Second comes the reaction of the antigen, which up to a certain point is of value for local lesions, calling attention to their existence. Finally the tuberculine reactions still remain the most dependable, being precise and practical, and give good immediate prognostic data, while they furnish the best guide to serotherapy through the allergy and anergy which they reveal.

Pellagra and Intestinal Worms.—Dr. Calmarza has recently published a thesis on pellagra, which is favorably reviewed in *La Medicina Ibera*. The chief feature in the thesis is the documentation of the claim that the children of pellagrous parents are peculiarly subject to intestinal worms, a fact which must possess significance. No particular worm is concerned, but all known common forms are equally present. The explanation of the phenomenon is not attempted, but it suggests the insect borne hypothesis more than another, although not forcibly. The author cites the opinion of no less an authority than Ramon y Cajal that pellagra represents an attenuation of lepra, which has required centuries for its perfection.

Book Reviews.

Diseases of Infants and Children. By Henry Dwight Chapin, A.M., M.D., Professor of Diseases of Children, New York Post-Graduate Medical School and Hospital; Supervising Physician of the Children's Department, New York Post-Graduate Hospital; Consulting Physician to the Willard Parker Hospital, etc., etc., and Godfrey Roger Pisek, M.D., Sc.D., Professor of Diseases of Children, and Attending Physician to the New York Post-Graduate Medical School and Hospital; Professor of Diseases of Children, University of Vermont Medical College; Visiting Physician to the Willard Parker and Riverside Hospitals, etc., etc. Fourth Revised Edition. With one hundred and eighty-two cuts and thirteen colored plates. New York: William Wood and Company, 1919.

It seems quite reasonable to suppose that the latest (fourth) edition of this book will "receive the same kind reception accorded it heretofore." Students are busy. Curriculums are jammed. Time is precious. This book is compact, well-illustrated, up-to-date, and it sacrifices surprisingly little to its brevity. Subjects which have received much attention from research men of late have been given new treatment in this edition. Such are acidosis, food allergy, epidemic encephalitis, functional heart disorders, spasmophilia.

One topic apparently too commonplace to receive much attention from other writers is brought forward for consideration by the authors of this book, namely, the diet of older children. It is a timely reminder of the fact that during the first year or two of life we see children fed to within a fraction of a calory, then to be abandoned to the dictates of their own capricious appetites.

The book has many of the virtues of the exhaustive text-book and none of the vices of the compend.

De l'Orthopedie Instrumentale Par le Docteur Gabriel Bidou Paris: Infirmerie des Orphelins-Apprentis d'Anteuil, 1919.

This little volume of 132 pages is illustrated with 20 photographic plates which show manikins, orthopedic apparatus, and patients with prosthesis. The author discusses the psychology of the cripple and his *morale*, electrodiagnosis, the mechanism of the articulations, fatigue, test apparatus, the bracemaker, choice of apparatus, working and *de luxe* prosthesis, walking with apparatus and prosthesis, the mathematics involved and compensatory methods of treatment such as gymnastics. The subject matter, according to the author, is new and intended to reduce the number of the helpless and aid the crippled, resected, and amputated.

Thoughts of a Psychiatrist on the War and After. By William A. White, M.D., Superintendent of St. Elizabeth's Hospital, Washington, D. C.; Professor of Nervous and Mental Diseases, Georgetown University; Professor of Nervous and Mental Diseases, George Washington University. New York: Paul B. Hoeber, 1919.

This little book of 137 pages is rightly entitled "Thoughts," for every line contains an idea. The rapidly developing general interest in scientific psychology will be greatly augmented by this lucid demonstration of the relation between individual mental conflict and periodical more or less widespread armed racial antagonisms, for the writer has remembered the intelligent layman as well as the technical student. The medical adviser may safely recommend this book to his patients, particularly to such as require slight mental readjustment, since it also touches upon many of the most vital angles of everyday life, placing them before the reader in a new and illuminating manner which can but help in the solution of many a mental problem. One of the most widespread social reactions of the war strain period has been an appalling disruption of homes due to a mild type of regression whereby certain lines of duty have been abandoned during a time of violent subjective mental conflict and replaced by such abnormalities or puerilities as dance halls or pictures shows in excess. The layman may not, at first, graciously receive the psychiatrist's statement that there exists a universal and natural conflict within each individual and between all individuals, *i.e.* between parents and children, between husband and wife, between races and clans, but, as he does come to accept these facts and learns to interpret and follow their signs, the plainer will his own reason and purpose lie before him. Psychology is assisting the individual to adjust himself to himself as well as to society, teaching him to accept the cards and to play the game.

The Elementary Nervous System. By G. H. Parker, Sc.D., Professor of Zoology, Harvard University. Philadelphia and London: J. B. Lippincott Company, 1919.

This, the second of the series on Experimental Biology being edited by Jacques Loeb, Rockefeller Institute, T. H. Morgan, Columbia University, and W. J. V. Osterhout, Harvard University, consists of 214 pages revised by Mrs. G. H. Parker and 53 line drawings illustrating the text contributed by Mrs. Donald E. Woodbridge. The study of Experimental Biology and General Physiology being one and the same science, the purely descriptive and speculative methods formerly employed have been abandoned and are already being replaced by those of the exact sciences with experimentation of a qualitative character. Very simple and purely technical discussions of the most elementary types are recorded in the present volume demonstrating the development of the nervous systems. The sponge *Stylotella* and the sea-anemone *Metridium*, in particular, are exhaustively examined and several jelly-fish and hydroids are also extensively studied. The generation-old hypothesis that nerve and muscle were simultaneously differentiated receives a blow in the demonstration that while sponges contain muscle, as yet no nervous tissue of any kind has been proven. Muscle, therefore, is of more primitive character than nerve. The point of biological interest between humans and these very much lower orders is to ascertain which of the various states of personality are elemental and what has been the probable line of evolution. Individual human personality is no longer considered as made up of various functions of the heart, liver, periphery, or other organs but to emanate definitely and solely from the nervous system, which is similar in neuronic arrangement in both the higher animals and lowly organisms like the earthworm, etc. Cellular elements perform various functions such as muscle control, sensation, intercommunication, intellectual operations, etc. These, in higher orders, operate through sense organs called receptors, which receive external stimuli and connect by nerve fibers with an adjustor or central nervous organ which directs the impulses toward the appropriate muscles, causing the animal to respond; or, in the most highly organized, the adjustor retains impressions of more or less permanence called memories, or it connects with effector elements which cause the animal to react. Even corals, jelly-fish, sea-anemones, etc., possess this neurological mechanism, though on an exceedingly simple plan.

Physical Diagnosis. By Richard Cabot, M.D., Professor of Medicine in Harvard University, Chief of the West Medical Service at the Massachusetts General Hospital. Seventh Edition. Revised and Enlarged. New York: William Wood and Company, 1919.

There is comparatively little that can be said of a new edition of Cabot's Physical Diagnosis that is not known to the medical profession generally. Its seven editions have appeared in a period of about fifteen years and during that time the book has become a very familiar one to students and practitioners. Its value is undisputed and this revision can only fix it more firmly in the opinion of the physician. Experience in France during the war has modified the author's ideas on the cardiac signs of nervousness, on hilus tuberculosis (peribronchial), on goiter heart, and on empyema. His beliefs about blood pressure and arteriosclerosis have undergone some change. All of these modifications have been embodied in the changed text and in addition a number of minor changes have been made. The book is slightly larger than the sixth edition.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

One Hundred and Fourteenth Annual Meeting, Held November 24, 1919.

THE PRESIDENT, DR. CHARLES H. PECK, IN THE CHAIR.

AFTER the transaction of the routine business of the society the following annual reports were submitted.

Report of Board of Censors.—Dr. LEWIS J. FRISSELL submitted this report, which stated that the board of censors had met regularly during the year and had transacted its routine business. No matter of vital interest had come before the society. The fraudulent medical advertisements, particularly in the foreign language newspapers, had formed a matter of study throughout the year, and through recommendation of the board of censors to the Comitia Minora and its subsequent adoption by that body, the Medical Society, through its counsel, had offered to aid the Health Department of the City of New York to suppress by proper proceedings such medical advertisements and to prosecute those against whom legal evidence might be found, who, by means of such advertisements, might be guilty of fraud or other illegal conduct. The report referred to the loss sustained by the society through the death of Dr. Floyd M. Crandall, who for many years had devoted himself to the activities of the board of censors.

Report of Committee on Membership—Dr. ANTHONY H. HARRIGAN presented this report, in which he stated that this committee held seven meetings, minutes of which had been recorded. They had recommended for election 80 candidates and recommended for announcement 117 candidates. They had introduced a method of transacting business which would obviate the delay which had sometimes occurred before the committee took final action on certain applications for membership.

Report of Committee on Public Health.—Dr. E. ELIOT HARRIS submitted this report, which consisted principally of a very comprehensive review of the narcotic drug situation. The report stated that under the Harrison Act 233,491 individuals or corporations were licensed to sell or prescribe narcotic drugs. Of this number 195,000 were physicians, and the remainder were dentists, veterinarians, druggists, hospitals, retail dealers, etc. Out of 4,092 patented and proprietary medicines and drug store preparations 1,098 contained one of the drugs mentioned in the Harrison Act. Of these 4,092 preparations 382 contained opium, 300 contained morphine, 280 heroin, and 136 cocaine. There was in the United States a decided narcotic drug situation, in comparison with other countries, for a report published by the Treasury Department, in 1919, after a year's investigation, showed that in 1910 the per capita consumption of opium in Austria was ½ grain per year, in Italy 2 grains, in France 3 grains, in the United States 36 grains per capita. The commission had sent out a number of questionnaires and the report based on these showed how little was known of the subject of drug addiction in the United States. The questions were addressed to 710 heads of health departments, to police departments, hospitals, and institutions. Of the replies received from health officials 338 contained information and 372 replied that they had no reliable data. Many answered the questions in a perfunctory way simply because they thought they ought to say something. After quoting at length from the report of the commission, the report of the committee stated that there was no doubt a large percentage of error in the replies to this questionnaire. Questionnaires were mailed to 3,000 State district and county health officers and 983 replies were received. Of these only 537 contained any information of value and many of the officers replied that they kept no records. Four hundred and twenty-five health officers stated that the physicians in their communities considered narcotic drug addiction a disease, while 542 stated that in their communities it was regarded as a vice. Therefore they were confronted with the same old question as to whether the drug addict came under the department of correction or was to be regarded as sick and cared for as a sick person. Estimates as to the number of drug addicts in the United States varied from 200,000 to 4,000,000. Under compulsory registration, in round numbers nearly 6,000 addicts registered in this city, which would make the percentage of drug addicts in New York City about one-eighth of one per cent. Heroin was unquestionably the worst of the drugs in regard to its baneful effects on the addict. Attention should be given the subject of absolutely prohibiting the manufacture of heroin on the part of both States and municipalities. The American Pharmaceutical Association, at its 1919 meeting, reiterated its resolution urging that the narcotic drug heroin be eliminated from all medicinal preparations and recommended that States pass laws prohibiting the manufacture of this drug. Heroin addiction, the report declared, was such as to make us endorse such action. There was a digest of the Harrison Law for the use of the medical profession. The law as it read, however, was not complete. There were a great many Supreme Court decisions on questions of interpretation of the law called T. D.'s decisions, which had been prepared by the Bureau of Internal Revenue. If an internal revenue officer came into a physician's office and examined his accounts he would enforce these Treasury Decisions, though they were not mentioned in the Harrison Law. It was important that every physician who prescribed narcotic drugs should obtain a copy of these decisions and familiarize himself with them. This pamphlet, about eight pages, defined exactly what was and what was not legal in accordance with these Supreme Court decisions. The constitutionality of the law had been upheld. The expression of "good faith" had never been defined, it was, in fact, the idea the lawyer got of the physician when he examined him on the witness stand as to whether he was prescribing a drug with the idea of curing the addict of his addiction or whether he was giving him the drug to make him comfortable. A physician was offending the law if he prescribed a narcotic drug simply for the purpose of making the addict comfortable. A bill providing for the institutional care of addicts was introduced into Congress on August 15 and reported favorably from the Senate, but had not been acted upon. Under this bill it was proposed that the State health boards should care for narcotic addicts and that the expense should be equally divided between the State and the Federal Government. The bill carried an appropriation of three million dollars for 1920 and for two million in 1921. No appropriations, however, were made. The report included detailed statistics regarding drug addiction in New York City compiled by the health department. According to these records from April 10 to July 10, 1919, the health department treated 2,723 patients, having been compelled to open a clinic to treat them because of the raids by the internal revenue officers which made it impossible for addicts to get their customary drugs. Of the 2,723 addicts, 2,216 were males and 507 females. The report of the United States Narcotic Drug Commission found that the addicts were about evenly divided as to sex. Among this number 850 were American, 210 Irish, 312 Polish, and there were smaller numbers from many other nationalities. Heroin was the drug of addiction in 1,878 cases, morphine in 493, both morphine and heroin in 36, and cocaine in 237. There were reasons, the report stated, why our State law should be modified. At present this law was not in harmony with the Federal law; it should be consistent with the Federal law and permit of cooperation between Federal and State officials. The law should be so constructed as to secure the maximum effectiveness in the control of drug addiction with the minimum annoyance and friction to the physician. As the Federal law was paramount and promised to be sufficiently effective the State law should be so framed as to correspond to the Federal law. The question as to the ambulatory treatment of drug addiction was still unsettled.

Report of the Counsel.—GEORGE W. WHITESIDE, Esq., submitted this report, in which he stated that during the past year he had made investigations and prosecutions against druggists, laymen practising medicine, corporations, unlicensed physicians, narcotic drug dispensers, chiropractors, neuropaths, and abortionists. He

had appeared before the Governor of the State on behalf of the society in opposition to the socalled Whitney Narcotic Act. He also prepared and read before the society a paper discussing the proposed Medical Practice Act introduced at the last session of the Legislature at the instance of the State Board of Regents. He had rendered opinions on the proposed amendments to the constitution of the society and on other matters that came before the board of censors and the Comitia Minora. He had frequently consulted with the various departments of State, city, and Federal Government, and had from time to time cooperated with these various departments in the enforcement of the laws and the suppression of unlawful and illegal practices. He had also from time to time during the year appeared before the State Board of Charities at hearings upon applications made by various societies that had applied to the State Board of Charities for licenses to operate clinics, hospitals, maternity associations, and the like. There were considered and reports made upon 38 cases of alleged unlicensed practice, and 18 cases were considered involving the conduct of licensed practitioners. Many other complaints of various kinds were received and acted upon. Mr. Whiteside pointed out that with the development of the laws affecting medical practice the function of the counsel's office for this society had undergone considerable change and extension. After reviewing these changes he expressed it as his judgment that this society should always interest itself in the prosecution of offenders against the Medical Practice Act, but that the investigation of such offenses, the obtaining of legal evidence, and the prosecution thereon should be conducted at public expense by the public officer charged with that duty. To obtain adequate official action along these lines would probably require additional legislation, and he recommended that such legislation be considered. The enactment in recent years of both Federal and State statutes imposing obligations and burdens upon medical practitioners had gone to such extremes that various Federal boards and State departments, without any general harmony of plan, controlled the action and conduct of physicians in their practice. The problems that thus arose must needs occupy the attention and thought of medical societies and their counsel. Various lay commissions and officers now largely regulated the practice of medicine. We had the Harrison Law regulating the dispensing of narcotic drugs; the Narcotic Law of this State, covering the same matter and imposing additional obligations; the Volstead Act affecting the rights of physicians to administer and prescribe alcohol; the Workmen's Compensation Law affecting the practice of physicians in treating injured workmen; the Public Health Law conferring wide powers on health commissioners, and numerous sanitary code provisions requiring reports from physicians in respect to communicable diseases, the operation of clinical laboratories, the rules respecting the establishment of quarantine, etc., and to this array it was proposed to add compulsory health insurance. They therefore had at present internal revenue officers and their agents, State narcotic commissioners, State prohibition commissioners, health commissioners, and State industrial commissioners, practically all of whom were laymen, each independent of the other, regulating the practice of the most scientific, highly specialized, and technical profession, the practice of medicine. To bring some harmony out of this confusion and an adequate participation by bodies of medical men in the administration of the medical features of these statutes medical men should now plan a constructive program of legislative action—one uniform medical practice code—the enforcement of which should be through properly constituted medical commission or board. The experience of past years had convinced the counsel, he stated, that his assistance in the coming year was needed in the legislative rather than in the prosecuting department of the society's work.

Report of Committee on Legislation.—Dr. GEORGE W. KOSMAK submitted this report, in which he stated that all bills of interest to the medical profession introduced during the one hundred and forty-second annual session of the Legislature of the State of New York were discussed at monthly meetings of the committee. A total of over 60 bills was thus studied, which, aside from those of minor or purely local interest, related chiefly to amendments to the Medical Practice Act, narcotic drug control, the changes in the sanitary code, to appropriations for the treatment of venereal diseases, and to compulsory health insurance. A bill providing for the annual registration of physicians was introduced and sponsored by the board of regents of the University of the State of New York, but failed of passage for political reasons. This action carried with it, however, a bill defeating the admission of chiropractors to the privileges usually conferred upon regularly licensed physicians. A measure providing for such annual registration would no doubt be introduced again. In order to avoid any further inconvenience to physicians by personal registration it was agreed by the representative of the State Board of Regents that such registration might be conducted through the medium of the county medical societies. Appropriations to continue the work of the commission of venereal diseases were passed. A number of amendments to the Workmen's Compensation Act were acted upon, relating chiefly to the compensation of injured employees. No direct provisions relating to the medical features of the act were considered and this portion of the law was in need of reformation and amendment. Thus far no concerted effort had been made to do anything in the matter. The report stated that perhaps the most important subject that had been dealt with in the Legislature were the measures making an attempt to provide for health insurance for the working people of the State, and reviewed the history of these measures. The presentation of the physicians' case was ably handled by Dr. Halstead, president of the State Society, and it might be confidently stated that the earnest efforts on his part resulted in a dignified and effective presentation of the case, for which credit must be given him. Dr. Kosmak expressed the opinion that bills along similar lines would be again introduced, if not at the next, then during the subsequent sessions of the Legislature. Thus far no health insurance measure which dealt with the profession fairly and justly had been introduced, and the chairman of this committee had consistently opposed every one of these bills at the hearing held in Albany.

Report of the Milk Commission.—Dr. WALTER LESTER CARR presented this report for the chairman of the committee, Dr. Rowland G. Freeman. The report stated that the past year had been one of difficulties for the milk producers as well as for every one else, with a result that there was some falling off in the amount of certified milk supervised by the commission, this diminution being from 14,000 to 12,000 quarts daily. The main reason for the diminution in the quantity of milk certified was that one large dairy producing 2,500 quarts daily suddenly ceased the production of milk last June. Other herds were being prepared for the production of certified milk, as the demand for certified milk exceeded the supply. The activities of the commission had continued on about the same basis as in former years. Two hundred and thirty-two visits to dairies had been made and 57 days spent in the laboratories. A review of the tuberculin tests in the certified herds under their supervision showed a much smaller number of reactors now than formerly.

Report of Public Health Education Committee.—Dr. ESTHER L. JEFFRIES submitted this report, which stated that during the year 1918-1919, after the signing of the armistice, the chairman of the committee studied the situation carefully and decided that it would be wiser not to undertake the presentation of a lecture course for reasons which were set forth, one of these being that the people were too restless and not in a mood to be lectured to, and, in addition to this reason, each member of the committee was still carrying on all the war work that any physician could possibly accomplish, and at the same time the personnel of the committee was reduced in numbers due to the absence of some of the members, who had gone to Europe on war work. Last spring there passed that beautiful and strong soul, Abraham Jacobi. He was a member of this committee since its inception and never failed to give the utmost interest and enthusiasm to this lecture work. The committee would soon begin its preparation for

the lecture course for the coming year 1920. Perhaps never in the history of this particular work had there been more need for education of the public along the lines of community and personal health than at present. It was the earnest wish of the committee that the entire membership of the County Medical Society help to spread the knowledge of health and protection from disease by each member making it a personal responsibility to send patients the program of this year's lecture course.

Report of Special Committee on Compulsory Health Insurance.—Dr. EDEN V. DELPHEY submitted this report. He stated that they had formulated certain amendments to the bill before the Legislature with the assistance of Mr. Whiteside in order that, should the bill become a law, it might be fair and equitable to the medical profession as such. These amendments were unanimously adopted by this society and were sent to the Governor and other interested persons; but, although they included all of the four fundamental propositions adopted by this society four years ago, namely, proper and adequate representation on the commission, etc.; panel of physicians; free choice of physician by the patient, and contracts for medical service with the panel, only one, free choice, was incorporated into the amended Davenport-Donahue bill. By direction of the Comitia Minora, the chairman of the committee took to Albany and delivered to Speaker Sweet, while sitting at his desk during a meeting of the Assembly, the nine specific objections which the committee formulated against the scheme of compulsory health insurance. The Speaker expressed his thanks for the communication, saying he would use it in the caucus that afternoon. The caucus was held, the bill was not reported to the Assembly, and therefore died in committee.

Report of Comitia Minora.—Dr. DANIEL S. DOUGHERTY submitted this report, which he stated was a résumé of the resolutions adopted by the society during the past year. The report showed that during the year the society had lost by death forty members, by resignation two, and by transfer eight. The present membership of the society was 2,840.

Plans for Reorganization.—Resolutions were adopted providing for the appointment of a committee to make a study of plans of reorganization and to submit them at the next annual meeting. On this committee the president appointed the following: Dr. Charles N. Dowd, Dr. Walter Lester Carr, Dr. Daniel S. Dougherty, Dr. Ten Eyck Elmendorf, Dr. Harry Isaacs, Dr. Samuel J. Kopetsky, and Dr. Frederic Sondern.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Charles H. Chetwood; *First Vice-President*, Dr. George Gray Ward; *Second Vice-President*, Dr. Orrin S. Wightman; *Secretary*, Dr. Daniel S. Dougherty; *Assistant Secretary*, Dr. J. Milton Mabbott; *Treasurer*, Dr. James Pedersen; *Censors to serve three years*, Dr. Arthur F. Chace, Dr. Henry H. M. Lyle, and Dr. Eugene Pool.

Pictures of Chinese Life.—At the invitation of the Comitia Minora, Dr. ORRIN S. WIGHTMAN, Major and Deputy Commissioner of the American Red Cross Commission to Russia, showed a unique series of moving pictures on Chinese life and customs, taken personally along the Yangtze-Kiang River and in Pekin.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, October 22, 1919.

THE PRESIDENT, DR. B. FRANKLIN STAHL, IN THE CHAIR.

Symposium on Intestinal Obstruction: Experimental Research.—Dr. J. E. SWEET of Philadelphia said that in acute high obstruction was seen a toxic condition developing in 18 hours which could be designated only as a tragedy. He thought it not unlikely that the solution of the problem of high obstruction would bring with it the answer to the question of intestinal stasis. Obstruction at the pylorus, the ileocecal region, in the sigmoid, or in the rectum, gave a picture of chronic disease contrasted with that of high obstruction. The acute problem lay, clinically, between the pylorus and the ileocecal region. It had been shown experimentally that the source of the poison could be limited to that portion of the small intestine of the dog corresponding roughly to the anatomical limits of the duodenum. The hypothesis developed was that the poison found in acute high obstruction was a normal product of the duodenum, and that it was normally destroyed in the jejunum. According to this theory, one was not dealing in acute obstruction with the formation of a new poison, but the obstruction had merely interfered with the normal process of the destruction of a poison normally formed and always present in the upper gut. There was no demonstrable source of toxin formation in the lower portion of the gastrointestinal tract from the beginning of the ileum perhaps to the anus. The actual source and character of the poison, however, had not been so easy to determine. It had been shown that the toxin belonged to the class of the socalled protein poisons, being related, therefore, to a class concerning which the chemists were not yet agreed. The poison found in high obstruction was related to the toxic proteoses and to the cause of death in anaphylactic shock. The pictures at autopsy of all the conditions were found to have much in common. A poison of the nature mentioned had been found in the content of the stomach, but this was not constantly observed. The stomach had been ruled out, as had also the liver. Other organs had been suspected and, as so often happened in research work, the farther the work was continued the more intricate did the problem appear, until suddenly, all became clear. While the illumination in this problem of obstruction had not yet appeared, the geographic source of the cause of the symptoms, the author said, had been experimentally located. The reasons for treatment were based upon the presence of an extremely powerful poison formed somehow in the gut above the obstruction; therefore, the necessity for the immediate operation; therefore, the value of the stomach pump.

Symptoms and Diagnosis of Acute Intestinal Obstruction.—Dr. HENRY D. JUMP presented a study of the general symptoms of acute intestinal obstruction without attempt to differentiate between the causes, or to localize specifically the portion of bowel affected. It was a lamentable fact that in most cases of acute obstruction no diagnosis had been made until the case was far advanced, and in many instances, not until the terminal symptom of toxemia had occurred. The mortality was stated to be above 40 per cent. in reported cases. Moynihan was quoted as believing that any mortality above 10 per cent. should be credited to delay. The burden of early diagnosis, in Dr. Jump's opinion, rested upon the family physician, as did also the responsibility of calling for surgical intervention. The alarming tendency to persist in medical treatment without relief he felt must be due to the rarity of the disorder and a consequent lack of estimation of its danger. Deaver and Ross had reported 276 cases in ten years from a busy clinic. The position surgically to-day regarding intestinal obstruction was said to be that of twenty years ago in connection with appendicitis when surgery was the last resort. While the medical man was justified in attempting to relieve obstruction by lavage and enema, purgation was dangerous and not to be used. Ochsner had said he had practically no mortality where cathartics had not been employed. Where they were used he believed they did great harm. Strangulated hernia was regarded by the author as the cause of the obstruction in more than half of the cases. In such instances diagnosis should encounter few difficulties, except in umbilical, ventral, and internal hernias. According to Coley, if the strangulation could not be reduced in five minutes by taxis it was unsafe to continue the treatment. Dr. Jump cautioned that in the presence of symptoms of intestinal obstruction an abdominal scar should suggest the possibility of the presence of post-operative adhesions, the cause in many cases.

The Treatment of Intestinal Obstruction.—Dr. GEORGE P. MÜLLER regarded obstruction in all its forms as essentially a surgical condition, and if diagnosed by the attending physician it should be passed on to the surgeon for treatment. In the mind of the majority of the profession, however, was rooted the habit of purgation upon the appearance of any abdominal lesion. Mostly the patient himself was at

fault, but sometimes the physician hesitated and waited for the effect of a dose of oil, salts, or calomel, or even all three. He believed that if laymen and physicians would consider acute abdominal pain as a contraindication, and not an indication for purgation, many lives would be saved. If operation must of necessity be delayed, the preoperative treatment was absolute withdrawal of food, water, and medication by the mouth, with the use of gastric lavage; the administration of water by the bowel, if it could be done satisfactorily, or by hypodermoclysis, if necessary; water must be given and retained. Enemata to empty the lower bowel and to encourage the escape of gas and other bowel contents would be desirable, but for the probable interference with the use of water. Enough morphine should be given to subdue pain, quiet the nerves, and to put the bowels at rest. Dr. Müller expressed his belief that morphine was absolutely indicated before operation in mechanical ileus, to eliminate violent peristalsis. He regarded toxemia and infection as responsible for the severe symptoms in intestinal obstruction. As a rule local anesthesia was to be preferred in all cases of intestinal obstruction. Young children with intussusception did best under ether. In old irreducible hernias with recent incarceration, gas oxgen-ether worked better than local anesthesia because of the edema of the tissues, and the presence of adhesions inside the sac hurt, and even shocked the patient during separation. Spinal anesthesia, skilfully administered, might be given the preference, but allowed to extend up to the splanchnic area became highly dangerous. The author admitted, however, a personal preference for ether when the diagnosis was doubtful, the patient not har dhit, and the exploration of the abdomen probable.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 20, 1919.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

Studies on Chronic Arthritis in the Army.—Dr. RALPH PEMBERTON of Philadelphia made this presentation by invitation, which consisted in an analysis of the observations made at United States General Hospital No. 9, at Lakewood, N. J., on 400 cases of chronic arthritis. The study included: (1) a statistical analysis in which the writer was assisted by Dr. J. C. Robertson; (2) observations on the basal metabolism, in which he was assisted by Edna H. Tompkins; (3) studies on the nitrogen, urea, carbon dioxide combining power, calcium, total fat, and cholesterol of the fasting blood; on the renal function; on the blood sugar, and on the sugar tolerance, in which he was assisted by Goodwin L. Foster; (4) studies in the relation of creatin metabolism to arthritis, in which he was assisted by Thomas E. Buckman, and (5) *x*-ray evidence, clinical considerations, treatment, and a clinical abstract of cases studied. Of the 400 cases, 256, or 64 per cent., had arthritis only; 112, or 26 per cent., had a combination of arthritis and myositis; 22 cases, or 5½ per cent., had myositis only; 7, or 75 per cent., had nerve involvement only, and 3 cases, or 0.75 per cent., were listed as doubtful. The average age of all patients was 28.26 years, while that of the worst cases showing the least improvement was 29.38 years. From statistics presented it was evident that chronic arthritis was one of the larger medical problems affecting the soldier. Soldiers developing it had had previous attacks with a frequency about five times greater than had soldiers admitted to hospital for other conditions at large. Exposure was the exciting factor in 56 per cent. of all cases. Critical examination of all cases revealed apparent foci of infection in 72 per cent. Although the etiological importance of focal infection, especially in civil life, was not to be minimized, it was clear that the present group showed a considerable independence of it. One hundred and eighty-four cases, or 46 per cent., recovered in the presence of demonstrable surgical foci. This was nearly three times the number which improved (63 cases, or 16.25 per cent.) after the removal of foci. The tonsils were most frequently the site of infection (52 per cent.), the teeth were next (33.5 per cent.); the genito-urinary tract came last (12.5 per cent.) and clearly played an almost negligible rôle in causing arthritis. The sites of most frequent involvement were the knee in 62 per cent., the ankle in 35.25 per cent., the hip in 33.75 per cent., and the shoulder in 31.25 per cent. All things considered, however, trauma to weight bearing parts caused by hiking, drilling, etc., played an importantly larger rôle than it did in civil life in determining the site involved. The basal metabolism was found to be normal in 80 per cent. of 29 cases studied. In 20 per cent. it was slightly below normal limits. The carbon dioxide combining power of the blood, the total fat, the cholesterol, and the calcium of the fasting blood were found to fall within the accepted normal limits. About one-half of 40 cases of arthritis studied showed an abnormally high value for blood creatin. Certain of these showed a decline in blood creatin coincident with clinical improvement. The urea of the fasting blood in 17 cases fell within normal limits. The nitrogen of the fasting blood in 67 observations on 57 cases fell within normal limits, with two exceptions. Studies of the renal function in 30 cases of arthritis of widely different types, by means of the socalled nephritic test meal, gave results which fell within the accepted range for normals. When compared with nine normals under similar conditions there was evident a slight lag in the elimination of water, nitrogen, and particularly of salt. In conjunction with the normal blood nitrogen and urea values mentioned above, it seemed fair to conclude that there was no important dislocation of the renal function in chronic arthritis. In studies on arthritis representing all degrees and stages of the disease it was found that there was a lowered sugar tolerance in a large proportion of cases. This lowered tolerance accompanied the great majority of severe cases and was roughly proportional to the activity of the arthritic process *per se*. It returned or tended to return to normal with convalescence or recovery. The return to normal was apparently independent of the type of therapy employed, but was most abrupt after the removal of causative foci of infection. In certain severe chronic cases from which all demonstrable foci had been removed, a lowered sugar tolerance seemed to persist. Apparent foci of infection, unproductive of systemic effects, were not necessarily accompanied by a lowered sugar tolerance. A lowered sugar tolerance from focal infection apparently accompanied the failure of the organism successfully to maintain its wall of defense. In this light a lowered tolerance became an intermediary step in the pathology of arthritis and possibly other conditions as well. A lowered sugar tolerance seemed to stand in relation to many infectious or inflammatory processes at large, and to depend upon more fundamental pathology than had been appreciated. It was also of more common occurrence than had been recognized. The lowered tolerance observed in some diseases and referred to them might have been due to focal infection rather than to the diseases under consideration. It was important that foci of infection be eliminated from consideration when miscellaneous conditions were studied in this regard. Critical examination of recruits for a history of previous attacks of arthritis would reveal cases most likely to develop it. It was reasonable to believe that rejection of this group, or at least the worst cases in it, would importantly reduce the incidence of arthritis in the army. A more conservative policy would segregate such cases, examine them for foci of infection, and remove such foci when found. This would have the added importance of prophylaxis toward the civil community. Various methods of treatment were discussed, including the removal of the foci of infection, rest and external treatment, including such measures as baking, massage, hydrotherapy, electricity, and the like, the injection of nonspecific foreign proteins, etc. Treatment of large numbers of cases, however, required methods of wide routine use. Local and external measures (physiotherapy) had unexpectedly large application because of the tendency of this group to improve under favorable conditions. They were also susceptible of easy routine employment. It seemed that in some cases of arthritis in this series six months or a year were needlessly lost. Earlier and more critical attention to focal infection, as a basis, together with large coincident use of local measures, would probably afford the routine therapy

best adapted to reach the greatest number of cases and should importantly curtail the existing invalidism. Many cases would require more individual attention, however, such as treatment by nonspecific protein injection or a restricted diet. Experience with treatment by a restricted diet corroborated, in the present group, the conclusions previously published regarding it. Such therapy found additional support in the studies on blood sugar, revealing a difficulty in the utilization of carbohydrate. It seemed clear that successes following this measure depended upon catering to a weakened function, of which the lowered sugar tolerance was one evidence. Treatment along this line had undoubted application in appropriate cases of chronic arthritis. The several measures of value in arthritis should be combined in their application to the group under consideration more frequently than obtained in the treatment of cases in civil life. The tendency to focus upon one measure often resulted in failure where the subsequent coincident use of several measures resulted in benefit.

Dr. JOHN H. RICHARDS said that one could not but be impressed by the great amount of work done in this study. Dr. Pemberton had sent to him his records, and he had gone over the work in detail. He felt that all future work done on this subject would use Dr. Pemberton's work as a basis. The subject of arthritis was most interesting on account of its obscurity and on account of the irregular behavior one constantly saw in the disease. One was very apt to become too enthusiastic over some plan of therapy that had seemed to have some merit in it, and hence he was glad to hear Dr. Pemberton say that his new plan of restricted diet was not applicable to all cases. In some few cases the removal of foci of infection was followed by complete recovery, while in others in which the foci were removed in the same manner the disease continued to progress, and in some cases no improvement was obtained no matter how treated. On account of limited experience he was not prepared to speak on the chemical phase of the subject, but might speak on the bacteriological side. He had made many complement fixation tests with all kinds of bacterial antigens, and considered this procedure an adjuvant in the study of the disease, but still in the experimental stage. A positive complement fixation test with *Streptococcus viridans* antigen was found in a very large proportion of the cases studied. On account of the frequency of foci of *Streptococcus viridans* infection it was difficult to interpret the fixation test. In 114 cases 14 gave positive blood cultures for *Streptococcus viridans*. A special technique was used in these cultures. The question arose whether this organism was common in the blood of those not suffering from arthritis, and whether its presence in the blood was coincident to the arthritis. Rosenau and others have done some excellent work on arthritis that would seem to have established a relationship between *Streptococcus viridans* and this disease. However, this infection did not represent the entire etiology of this type of arthritis. Dr. Pemberton had demonstrated a metabolic factor, and he had found that starvation was beneficial in certain selected cases. This brought to his mind the fact that frequently *Streptococcus viridans* was found in the stool in these cases, and he thought that the benefit following this starvation was possibly the result of limiting the growth of this organism by this means. He had repeatedly seen marked improvement follow a change in diet so that the residual pabulum was inimical to the growth of these organisms. This statement was supported by the fact that *Strcptococcus viridans* grows best on sugar media of just the right degree of acidity. Arthritis was a disease prone to changes without apparent causes, and subject to frequent remissions and relapses. Hence the tendency was to credit improvement to the treatment used just before the remission. Dr. Pemberton's demonstration of lowered sugar tolerance in arthritis was most interesting, and might lead to a better understanding of the disease.

Dr. WILLIAM C. THRO said that one of the interesting subjects in medicine was the etiology of disease, and, with the trend of modern medicine toward prevention, such studies as those just given were of special interest. Dr. Pemberton had brought out the fact that exposure was one of the predisposing causes of arthritis. In this connection it was of interest that some investigations published in the *Journal of Medical Research* had demonstrated that chilling of the body caused ischemia and that this lowered the resistance of the surface of the mucous membranes so that bacteria more easily entered. This was contrary to the generally accepted view that chilling of the body causes a congestion internally. Dr. Pemberton had done a great deal of chemical work, most of it showing comparatively normal chemical conditions in arthritis except for the lowered sugar tolerance and the disturbance of the creatinine nitrogen. He had shown that even in spite of unavoidable neglect many cases recovered and that 46 per cent. of the cases recovered in the presence of demonstrable surgical foci. These figures could always be quoted to those who boast of the cures due to vaccine therapy. Dr. Pemberton had not considered the intestines as a portal of entry or a focus of infection. It was conceivable, if one considered the great length of the intestines, that it was possible that some toxins produced might be absorbed through the wall of the intestines. He had omitted the subject of the bacteriology of arthritis, saying that this field had been pretty thoroughly studied. It would have been a great opportunity for Dr. Pemberton to make a bacteriological study of arthritis, for to his mind this question was far from settled; in fact, Dr. Pemberton practically admitted that such a study would have been of value. Dr. Richards said that he found 14 positive blood cultures out of 114 taken in arthritis. Moon and Edwards found that in 25 out of 83 cases there were various organisms present, such as a nonhemolytic coccus, the *B. capsulatus mucosus*, *B. welchii*, *B catarrhalis* and the gonococcus. Thus far the work published seems to prove that the nonhemolytic streptococcus was the microorganism most often concerned. Regarding therapy, in the Laboratory of Clinical Pathology a great deal had not been done with nonspecific proteins and Sollman looked on these injections as causing more of a pharmacological than an immunological reaction. They had employed vaccines for a considerable time and had applied the rules used in the immunization of animals, using saline suspensions at regular intervals and in small doses at the beginning. As was well known, with foreign proteins very severe reactions were often obtained when they were injected into the venous system. This investigation was so complete in some parts that it would be unnecessary to do further research upon them.

Dr. LEWIS A. CONNER said his discussion confined itself chiefly to some account of certain features of the work rather than a critical discussion of the results, because there was no subject in internal medicine on which he felt his ignorance quite so keenly and no type of cases in the presence of which he felt so helpless as these cases of chronic arthritis. He had been privileged to follow the work of Dr. Pemberton and his associates at General Hospital No. 9. Those who were in the surgeon general's office thought they were very fortunate in being able to accumulate all these cases of arthritis in one hospital and to get Major Pemberton and his associates together to carry out these fundamental studies into the nature of this disease. As had been said, no such accumulation of cases had been possible since the Civil War, so far as he knew. Not only was this a great opportunity in view of the great number of cases that were gotten together, but it was an especially valuable opportunity by reason of the fact that these cases occurred in young people and were for the most part early cases representing the active, living disease rather than merely its dry bones, as was so often the case in patients seen in civil practice. It was hardly necessary to point out the importance to the army of a serious study of this disease when it was known that there was an estimated incidence of 40,000 cases of arthritis a year for our army of 4,000,000 men. Not only were there a great number of cases, but the disability in each case was apt to be very long, usually for many months. It was because of the fact that these were young, early cases that it had been possible to get such results as were obtained at Lakewood, where, as Dr. Pemberton had shown, over 77 per cent. of the cases were discharged recovered. This was a proportion very much greater than that which they were accustomed to expect among older people in civil

life. One of the most striking things was that over 40 per cent. recovered in the presence of demonstrable foci of infection. It had been of immense interest to him to find that Dr. Pemberton, in his study of young, early cases in which infection would seem to play a much more important rôle than in the very chronic cases of later life, should have been brought to conclude that focal infection did not cover the whole subject of the pathogenesis. It seemed to him that any one following his own cases critically must have reached the same conclusion. Some cases in which the foci were removed did well and some cases showed no response whatever to the removal of such foci. Dr. Pemberton had been forced to conclude that in many cases some other factor must play an important part in the causation of the disease. The suggestion that in certain cases focal infection might act indirectly by causing a disturbance of the carbohydrate metabolism was very interesting and seemed to have considerable evidence to support it. As for the work in Lakewood, it was well to emphasize the fact that these metabolic studies had been carried out by a staff of exceptionally well qualified workers, and they could feel perfectly sure that no study had ever been undertaken under more favorable conditions and where the results were likely to be more accurate. The whole subject had been approached in a most open-minded way. No effort was made to work out a pet theory or to establish a particular method of treatment. It seemed that this work must furnish a starting point for all subsequent work of this sort by reason of its thorough and comprehensive character.

Dr. PEMBERTON, in closing, said there was no field in which it was so easy to reach half baked conclusions as in this, and he wished to emphasize that he had been most dispassionate in the interpretation of results. They did not claim that their lines of treatment were by any means final or infallible. If in any statement he had appeared to be too enthusiastic he assured them that when such statements were published they would be accompanied by qualifying clauses.

THE AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-sixth Annual Meeting, Held at Atlantic City, June 14, 16, *and* 17, 1919.

THE PRESIDENT, DR. GUY HINSDALE OF HOT SPRINGS, VA., IN THE CHAIR.

(*Concluded from page* 991.)

Report of the Work as Seen in Certain Spheres of the Office of the Surgeon General.—Lieut.-Col. CHARLES W. RICHARDSON presented this paper, in which he related that just before the declaration of war, April 6, 1917, he had been appointed a member of a committee of three, representing the American Otological Society, American Laryngological Association, and the American Laryngological, Rhinological, and Otological Association for the purpose of conferring with the surgeon generals of the army and navy to ascertain wherein the members of these bodies could be used to the greatest advantages in these services. This committee, consisting of Dr. Harris P. Mosher of Boston, Dr. Burt G. Shurley, and the writer, was the second organization of specialties accepted and put into action by the medical section of the Council of National Defense. The activities of this section consisted in the listing of the known specialists in these branches, preparing and sending out questionnaires, and maintaining a card index and files according to the replies to the questionnaires. Through this method they obtained the request or consent of several hundred specialists practicing otolaryngology to enter the service as members of the Medical Reserve Corps. This performance of duty seemed in statement very simple, but in actuality it entailed quite a laborious effort, requiring the sending out of 5000 questionnaires and classifying the replies. During the month of July, 1917, the Division of Surgery of the Head was created in the Surgeon General's office, with Lieut.-Col. Theodore F. Lyster as chief, and the Section on Otolaryngology came under this Division with the writer as major in charge. At the time of his induction into the office of the surgeon general, the presiding genius of this important bureau was Maj.-Gen. William C. Gorgas. The officers in charge of the various divisions were men distinguished in the regular service for their organizing and administrative ability. The heads of some few of the special divisions and the assistants in all divisions were men famous in medicine who had been inducted into the service from civil life. How well all these men lived up to what was expected of them was thoroughly demonstrated by the smooth running of the office and the wonderful results attained. The collective work and the attendant results would only be fully told when the surgical and medical history of the war was published. The writer then described the work of the administrative, hospital, laboratory, finance, and supply divisions. The administrative work had grown from a few offices in the State, War, and Navy Building, in charge of six officers, with a force of about 100 civilian clerks, until by the end of the year 1917 the staff consisted of 165 officers and 535 clerks, occupying the whole of five buildings and parts of two others. At the present time the same organization had grown to a point occupying 225,000 square feet of space, with over 250 officers and nearly 1300 civilian employees. Under war pressure as many as 6000 telegrams had been received in the surgeon general's office in a single day. It had been the policy of the surgeon general's office to utilize the services of the specialists as far as possible in the line of his specialty. The results of this arrangement had proven eminently satisfactory and advantageous to the soldier patient, as well as to the medical officer. It marked a signal advance in the administration of military medical affairs. The Hospital Divison, organized in May, 1917, constructed, organized, and supervised the military hospitals of all kinds, organized hospital trains and ships, sanitary trains, sanitary squads for lines of communication, convalescent camps and depots, and reconstruction hospitals, schools, and workshops. It had accomplished its manifold purposes so admirably that we had now in this country well-equipped base hospitals and all facilities were at hand for the operative and other treatment of the most complicated cases in a manner not to be surpassed by the best civil hospitals. The Hospital Division had organized and supervised all the provisions for the after care and rehabilitation of those who needed to be made ready to reenter civil life. The number of beds in army posts at the beginning of the war was 6544. The number of beds in the service of the army in the United States at present was 79,077. In November, 1918, there were 236,000 hospital beds available in France for the American Expeditionary Forces, and 121,883 hospital beds were available in the United States, a total of 358,883. In November, 1918, there were 193,448 patients in the A. E. F. hospitals in France, of which 99,000 were injuries; there were 70,000 in our base hospitals in the United States on the same date. The Laboratory Division had supplied our army hospitals with facilities for doing laboratory work for the treatment of acute infectious diseases and diseases of metabolism. Through the number of its experimental workers it had obtained many new ideas, and a great many promising leads. This department had also furnished the vaccines for the entire army, navy, and national guard. It also furnished vaccines for the contractors to be used upon the men in connection with army work. All these vaccines were produced at the Army Medical School. The Laboratory Division also did work in the army cantonments, where it worked in cooperation with boards of health and municipal governments. The Finance and Supply Division had to purchase, inspect, and supervise transportation, issue and account for the drugs, appliances, instruments, dressings, antiseptics, and the thousand odds and ends necessary for the sick and wounded of an army of over a million. Colonel Richardson described in detail the work of these divisions and commended the efficiency of the organization of the surgeon general's office.

A Case of Enlarged Thymus Gland.—Dr. RICHARD COLE NEWTON of Montclair, N. J., reported this case, and made some remarks on status lymphaticus. He

stated that the patient was 20 years of age, weighed 145 pounds, and gave a negative family and personal history. After exhausting labor he jumped into the lake and swam a considerable distance, and two weeks later began to complain of lassitude and loss of muscular vigor, with some dyspnea. In a short time his neck, upper chest and shoulders, especially the right, began to swell with a soft edema. There were also a number of maculae, dark purple in color, and about the circumference of a dime, in clusters over the upper sternal region. The dyspnea and loss of muscular tone gradually increased. A loud double heart murmur developed, and the patient seemed very sick. He was taken to New York to a consultant, who thought there might be an aneurysm and advised an *x*-ray. This was made, and the thymus gland was found so enlarged that it covered all or nearly all of the anterior surface of the pericardium. The patient received six *x*-ray treatments at weekly intervals, and apparently recovered and resumed his previous habits. In about a year the edema and dyspnea returned and the *x*-ray treatment was resumed. After nine exposures the patient was again free from edema. The onset of the second attack was preceded by a sharp run to catch a train, and it was believed that this exertion induced the recurrence. The heart murmur, although milder than formerly, was still present. The improvement after the second series of *x*-ray exposures was only temporary. Two stereoscopic plates of the chest showed practically the same condition as the first two taken some months ago as regarded the thymus, although the thymus was possibly not as large as in the first pictures. There was a distinct cloudiness of the left lung and the shadows of the bronchi in the apex were clear to the periphery on the first and second interspaces. In the lower portion of the upper right lobe the shadows were very dense. This meant that there had been an involvement of the lobe with tuberculosis. The patient gradually lost ground and developed an aneurysm of the aortic arch with protrusion of the upper sternal region and a distinct tracheal tug. Edema of the feet, ankles, hands, and wrists developed, and excrutiating pain of the right arm and shoulder. The patient gradually became helpless, and died March 31, 1919. Nothing abnormal was found in his urine. The writer reviewed the minute anatomy, the growth, involution, physiology, and pathology of the thymus gland. He said that in many sudden deaths in which there was no apparent cause, and also in seriously diseased conditions, an enlarged persistent thymus had been observed either along or coexisting with certain abnormal conditions in the lymphatic system and other bodily organs. These changes as a whole were originally grouped together under the title of status lymphaticus, but recent observers had divided this syndrome into three subdivisions, as follows: status thymicus, status thymicolymphaticus, and status lymphaticus. These three conditions were so named according to the size and the apparent activity of the thymus. In status thymicus the size of the thymus was usually larger than in status thymicolymphaticus and was not accompanied by marked changes in the lymphatic system. In the status thymicolymphaticus there was a general hyperplasia of the lymphatic tissues throughout the body, especially the tonsils, and the lingual, pharyngeal, and cervical glands. In the status lymphaticus, the thymus was not enlarged and might even be subnormal in size, nevertheless the size of this organ was probably not of itself a criterion of the systemic lesions present in these three allied conditions. Most of the cases of so-called thymic death occurred in adults, but some had happened in infancy and early life, and probably some of them were not attributed to the right cause. Among the diseases having a more or less close relation to the thymic and general bodily conditions under discussion were exophthalmic goiter, Addison's disease, diphtheria, tetanus, eclampsia, eczema in children, myasthenia, osteomalacia burns, etc. Among practical conclusions that might be drawn from a study of thymic conditions were that the *x*-ray had removed some at least of the uncertainties of the diagnosis and had seemingly favorably influenced the treatment. The fear that operation would be almost inevitably fatal had been largely removed by the few successful cases reported. These were all in infants, so far as the writer could ascertain. Whether adults with enlarged thymus should be submitted to the risks of operation had not apparently been determined. There should be a more strenuous effort made to ascertain whether something definite could not be done to benefit these cases as a whole by hygiene and diet rather than by medication. It was quite likely that anomalies in the structure and size of the thymus were due rather to a constitutional condition than to primary disease of the organ itself. Ewing emphasized the fact that there were stages of hyperplasia and hypoplasia of the thymus and the lymphatic system. These stages, if properly carried out, seemed to be normal to the growth and development of the human body. Interference with or undue activation of these processes appeared to cause or at least accompany the condition which was known as status lymphaticus, and this was characterized, generally speaking, by some permanent bodily defects like thin arterial walls and small heart; an excess of lymphoid tissue might or might not be characterized by the typus feminis, in the conformation of the body. The patient who was the subject of this report did not evince these outward physical characteristics, but he had the tendency to edema and to aneurysm so well marked in many of these cases. It was fair to suppose that the fairly large thymus in this case would have atrophied in time and had the aneurysm not occurred as a complication he might have enjoyed a number of years of useful life. The aneurysm was probably caused by over exertion in a person with congenitally weak and attenuated arterial walls. That the *x*-ray was so efficient at first and so ineffectual afterwards was, it might be assumed, because at the first *x*-ray treatment the aneurysm had not developed, but at the second it had become the controlling factor in the morbic condition.

The Treatment of Tuberculosis in Returned Canadian Troops.—Dr. J. Roddick Byers of Ste. Agathe des Monts, Canada, presented this communication, in which he stated that the treatment of tuberculosis in the returned Canadian troops devolved upon the Department of the Soldiers' Civil Reestablishment of Canada, created by Act of Parliament. Very full authority had been given this department. The following were responsible for the treatment of tuberculous troops: (1) Headquarters medical staff, director of medical services, deputy director of medical services, inspector of medical services, officer in care of medical supplies and equipment; (2) unit medical staff, unit medical director and two or more assistants, specialists for examinations of the lungs, specialists for eye, ear, nose, and throat, surgeon, physician and others; (3) the sanatoria staff as outlined later; (4) medical representatives, physicians in the outlying places who represented the unit medical director in taking care of old cases that might be living at home. In addition it must be remembered that the medical branch of the department could when necessary and with authority granted call upon the other branches, such as the engineering, purchasing, etc., for the necessary assistance and equipment of the institutions which tended for the welfare of the patients. For the purpose of administration the country had been divided into geographical areas, termed units, which were administered by officers representing the heads of the various departments, thus establishing the chain of responsibility between the sanatorium, hospital, and the minister of the department. As far as possible all unit officers had their business quarters in a common building; in this way delay in dealing with a soldier was reduced to a minimum. At the present there were nine units extending from the Atlantic to the Pacific Ocean, in which were established 29 sanatoria, having a total capacity of 1811 beds, and in which were 1730 cases of tuberculosis under treatment on March 1, 1919. From the beginning of the war a total of 5831 cases had been treated with excellent clinical results. The soldier was offered a full course of sanatorium treatment, with the object of obtaining at least an apparent arrest of his disease and testing out his resistance by suitable exercise before discharge from treatment was effected. During the treatment the soldier received the same pay as though he were in the army, and this put him at rest so far as financial burdens were con-

cerned. He was not, however, forced to take treatment, but he seldom refused. After a soldier had completed his course of treatment and his disease was apparently arrested, he was discharged from treatment and received a pension on a basis of 100 per cent. disability for the first six months after leaving treatment. At the end of this period he was reexamined, and his pensional disability estimated by a board of medical experts under the Board of Pension Commissioners. Or, second, he might become a class 1 "outpatient" for observation purposes, receiving his pay and allowances as if in the sanatorium. As far as tuberculosis was concerned, very few entered this class and the conditions warranting it must be exceptional. Following the sanatorium treatment, if it was found that the occupation of the soldier prior to enlistment was of such a nature as to be unsuitable to a man with latent tuberculosis, and with the idea of avoiding relapse, a soldier might receive vocational training along lines suitable to his condition. While taking the vocational training, he was paid the equivalent of what he received while under treatment, with an amount for living allowance added. Complete records were kept on standardized forms, and the necessary reports and returned passed at proper intervals to the high offices, and from one institution to another as necessity required. The rules and regulations of the sanatoria were for the most part based upon the teachings of the late Dr. Trudeau of Saranac Lake School, and had been thoroughly systematized throughout the country, so that a patient passing from one institution to another experienced little or no change in the methods of his treatment which tended to increase his confidence and help him in his fight for renewed health. Early in the war it was found that the prewar sanatorium methods were inadequate for the treatment of soldiers returned from service, being too monotonous, and resulting in 15 per cent. discharged for insubordination, and 33 per cent. refusals of treatment. This situation was met by the introduction of the standardized method of treatment and the introduction of occupational therapy, whereby patients were divided into three main classes: (*a*) Infirmary cases—Those patients who were suffering with the disease in the acute and toxic stage, and in consequence were confined in bed throughout the day. These patients were allowed to knit, draw, embroider, crochet, do cardboard work, weave raffia, and study in moderation and under strict clinical control. This work was in no way obligatory. (*b*) Porch cases—These were allowed to attend the meal table three times daily, wash themselves, perform other daily habits, and rest in the open air in reclining chairs. They were allowed to do more work of the sort given Class A, and as they began to increase in strength they undertook slightly heavier work, such as reed basketry, penmanship, telegraphy, and class study. Class D—These were the exercise and workshop cases. As the clinical evidences pointed to the disease becoming arrested, the patients passed into this class, which was divided into six subdivisions, according to the periods of time allotted to exercise, the first group getting fifteen minutes, the second thirty, etc. A man entering class C was allowed fifteen minutes' slow walking morning and afternoon; if he showed improvement he was advanced fortnightly into the succeeding divisions. While attending the shop, patients were given their choice of certain arts and crafts, and in general school instruction following the qualifications required by the Civil Service department of the Canadian Government. In addition, educational and recreational entertainment was provided. All the medical and hospital details of a properly conducted sanatorium were carried out, the occupational therapy being merely an adjunct to the medical organization. Following discharge from the sanatorium, the social workers followed up the patient and reported at intervals on his welfare. Should relapse follow at any time he could be admitted immediately to sanatorium treatment. Up to March 31, 1919, the total number of cases of pulmonary tuberculosis was 5831, of which 3614 were discharged, and 487 died, leaving 1730 under treatment. Of those discharged 12 per cent. had apparently arrested disease; 9 per cent. had quiescent disease; 41.5 showed marked improvement; 7.3 per cent. showed no improvement, and 6.3 per cent. refused treatment; 4.6 per cent. of the cases were not tuberculous; 17 per cent. were not recorded.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

RÉNÉ THÉOPHILE HYACINTHE LAENNEC

AND

THE HUNDREDTH ANNIVERSARY OF HIS BOOK ON MEDIATE AUSCULTATION.*

BY S. ADOLPHUS KNOPF, M.D.,

NEW YORK AND PARIS.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

IN this period of reconstruction and at a time when the relations between French and American physicians have become more close than ever before as a result of their sufferings, mutual sacrifices, and labors, common aspirations and hopes in the world war, I believe it to be most timely to join with our confrères across the water in paying tribute to one of the greatest French physicians of the last century, and recall the labors and achievements of the immortal Laennec.

For a lengthy biography of this great man I refer my readers to the writings of Forbes, Austin Flint, James J. Walsh, Edward O. Otis, William Osler, and others.† It is my purpose on this occasion to refer only to a few outstanding events in the career of this great man and give a brief translation of the address delivered recently at the anniversary of the publication of Laennec's book, by my distinguished teacher, Professor Maurice Letulle of the Faculty of Medicine of the University of Paris.

Laennec, who even to-day must be considered as one of the greatest figures in scientific medicine, was born February 17, 1781, at Quimper, in Brittany, France. His father was a jurist and poetically inclined. His grand uncle the Abbé Laennec, was mainly responsible for his preliminary education. Later on he studied with his uncle, Dr. Laennec, who was a member of the faculty of medicine of the University of Nantes. In the year 1800, the young man went to Paris and matriculated at the Faculty of Medicine. He distinguished himself as a student from the very beginning and received two first prizes before graduating, one for medicine and one for surgery. In 1804 he wrote two theses for his final degree, one in Latin and one in French; both were tributes to Hippocrates for whom Laennec had the greatest admiration. His favorite master in Paris was Corvisart, to whom he became assistant. In 1812 he was made physician to the Baujon Hospital and in 1816 took charge of the service at Necker Hospital.

James J. Walsh, in his admirable eulogy of Laennec, entitled "Laennec: A Martyr to Science," speaks of Laennec's clinics at the Necker Hospital as follows: "It was here where Laennec was destined to bring his great researches to a successful issue. It was to the Necker Hospital, before long, that students from all over the world flocked to his clinical lectures, in order to keep themselves in touch with the great discoveries the youthful master was making. In spite of rather delicate health Laennec fulfilled his duties as physician and professor at the Faculty of Medicine and College of France with scrupulous exactitude and with a self-sacrificing devotion that was, unfortunately, to prove serious for his health before very long."

The one most important event in Laennec's short but remarkable life was the discovery of the stethoscope, of which he wrote:

> In 1816 I was consulted by a young person who was laboring from the general symptoms of a diseased heart. In her case percussion and the application of the hand (what modern doctors call palpation) were of little service because of a considerable degree of stoutness. The other method, that namely of listening to the sounds within the chest by the direct application of the ear to the chest wall, being rendered inadmissible by the age and sex of the patient, I happened to recollect a simple and well-known fact in accoustics and fancied it might be turned to some use on the present occasion. The fact I allude to is the great distinctness with which we hear the scratch of a pin at one end of a piece of wood on applying our ear to the other.
>
> Immediately on the occurrence of this idea I rolled a quire of paper into a kind of cylinder and applied one end of it to the region of the heart and the other to my ear. I was not a little surprised and pleased to find that I could thereby perceive the action of the heart in a manner much more clear and distinct than I had ever been able to do by immediate application of the ear.
>
> From this moment I imagined that the circumstance might furnish means for enabling us to ascertain the character not only of the action of the heart, but of every species of sound produced by the motion of all the thoracic viscera, and consequently for the exploration of the respiration, the voice, the râles, and perhaps even the fluctuation of fluid effused in the pleura or pericardium. With this conviction I forthwith commenced at the Necker Hospital a series of observations from which I have been able to deduce a set of new signs of diseases of the chest. These are for the most

Sir William Osler: "Men and Books, VIII, Letters of Laennec." *Canadian Med. Assn. Journal*, Toronto, 1912, II.

part certain, simple and prominent, and calculated, perhaps, to render the diagnosis of the diseases of the lungs, heart, and pleura as decided and circumstantial as the indications furnished to the surgeon by the finger or sound, in the complaints wherein these are of use.

As Walsh very justly said, when relating this important event as described by Laennec himself, "This is the unassuming way in which Laennec announced his great discovery."

After three years of constant and careful clinical research work, Laennec published his book on mediate auscultation, the full title of which is "L'Auscultation Médiate, ou Traité du Diagnostique des Maladies des Poumons et du Cœur, fondé principalement sur ce nouveau moyen d'exploration." A second edition appeared in 1826, and the first English translation came out in the same year under the title, "A Treatise on Diseases of the Chest and

Fig. 1—Réné Théophile Hyacinthe Laennec.

on Mediate Auscultation; Translated from the French by John Forbes; London, I. & G. Underwood, 1826." Three editions followed, the fourth published in London by Longmans in 1834, and many others have since been published in England, America, and other countries.

Six months after the second French edition of his book was published Laennec passed away in his native town on August 13, 1826, at the age of 45. From the description of his disease there is no doubt that he died of pulmonary tuberculosis. Unfortunately old-time treatment, venesection, was resorted to and our modern methods of dealing with tuberculous patients, which are the very opposite of what it was a century ago, were not known. Laennec's own description of an early infection to which we believe we can ascribe the origin of his tuberculous disease is very interesting. He states in the Chapter on Consumption, that twenty years before the publication of his Treatise on Mediate Auscultation, while examining some verterbræ which contained tubercles, he slightly grazed the forefinger of his left hand with the saw. After the lapse of about eight days there a small roundish tumor appeared in the place scratched which exhibited internally a firm yellowish consistence, in every respect like a crude tubercle. Twenty years later Laennec was obliged to give up work because he was suffering from all the symptoms indicating a pulmonary tuberculosis.

Laennec's life was short, but in the relatively few years of his professional activities he accomplished marvelous things which will forever make him one of the most illustrious figures in scientific medicine and one of the great benefactors of mankind. To judge by the rich clientele which he enjoyed for a number of years, Laennec must have been a very much liked and very successful physician. He was, however, above all an ideal clinical teacher. His pupils were deeply attached to him, and he, in turn, showed great affection for them. In the preface to his epoch-making book on Mediate Auscultation, he reverently and thankfully refers to his own teachers, Bayle and Corvisart. He writes with especial feeling of Corvisart and calls himself the latter's disciple. Laennec gratefully recognized the cooperation of his pupils and speaks of them in generous and affectionate terms. He mentions them all, interns, externs, and simple students with equal praise. Among them were Rault, Meriadec, and Ambroise Laennec, Dalbant, Baumes, and Toulmouche. Of these young coworkers he said: "Without their help, their untiring industry and labors I could not have attained the results in the comparatively short period which I had devoted to these researches."

Laennec was profoundly religious, and to his death a devout Catholic. His remains lie in the beautiful little cemetery of Ploare near Douarnenez, where, on October 13, 1919, religious services were conducted by the Rt. Rev. Abgrall, Canon and Chaplain to the Quimper Hospital, who was largely responsible for starting the movement for the anniversary celebration of Laennec. On October 12th, the day preceding the religious ceremony, a general celebration took place in front of the statue of Laennec in the town of Quimper. The College of France had sent Professor Gley as its delegate; the Faculty of Medicine of the University of Paris was represented by Professor Maurice Letulle; Professors Rappin and Rouxeau represented the school of medicine of Nantes, and the General Association of Physicians of France had sent its president, Dr. Bellencontre of Paris. The spokesman for the local physicians was Dr. Collin of Quimper. All the speakers paid glowing tributes to the life and labors of the great physician.

The address delivered by Dr. Letulle on that occasion* is of such beauty and shows such depth of gratitude that I am sure the Section of Historic Medicine of this great Academy will be glad to hear it, even if only in abbreviated form. Professor Letulle called Laennec's book: "A masterpiece, the beauty of which, far from being diminished by age, increases in grandeur as time goes on. Modern medicine recognizes its Magna Charta in Laennec's

*La Presse Médicale, Paris, November 15, 1919.

book on mediate auscultation and the medical world at large piously preserves its unalterable pages. Laennec's book, 100 years old, is as new to-day as it ever was. It attracts the reader and causes him to meditate. In 1819 when this book appeared, there had arisen a young generation of French physicians, such as Cruveilhier, Andral, Louis, Recamier, Piorry, Gendrin, Bretonneau, Bouillard and others all eager for clinical and pathological research work, but it seemed that they had no leader to guide them until Laennec came forward and proved the master whom they had been seeking. Laennec had already distinguished himself by his studies in pathological anatomy, and a number of publications on this subject had given him an enviable reputation. He was attending physician to the Necker Hospital, where his clinical teachings at the bedside attracted wide attention and his ever-increasing classes did not fail to also arouse the jealousy of his older colleagues. His clinic was not officially recognized as one of the clinics of the Faculty, for even in those days there was already a distinction between "des officiels et des non officiels."

"The book came as a sudden revelation. It described with wonderful precision a number of diseases which heretofore were only suspected or totally unknown. The perusal of the book shows the practitioner how he can study the diseases of his patients by a simple, practical and easy technique. In a few hundred pages Laennec in his admirable style describes the microscopic alteration of the lung and pleura in various diseases: pneumonia, gangrene, edema, emphysema, dilatation of the bronchi, etc."

"Although a master of pathological anatomy, Laennec was above all a clinician and considered himself such. One fine day he invented an instru-

Fig. 2—Laennec in 1816 at the Necker Hospital, auscultating a phthisical patient in presence of his pupils. In his left hand he holds his stethoscope.

ment which helped him in his clinical observations and investigations, and the stethoscope saw the light of day. In the hands of such a practitioner mediate auscultation caused a revolution in the diagnostic art and a new world opened itself to the clinician Laennec. He plunged into the study of auscultatory signs with ardor and enthusiasm and in less than thirty months he had completed his marvelous work on the diagnostic signs which could be isolated with the aid of a stethoscope.

Letulle calls Laennec's achievements the work of a giant in intellect and continues: "It is difficult to know what to admire most in this unique personage—the pathologist who spent the best years of his youth in the post-mortem rooms, studying and writing down the wonders of pathological anatomy, or the clinician who, with the aid of a wooden cylinder acquired the skill of a marvelous diagnostician. In 1819 Laennec published in book form the results of his pathological and clinical observations. In this volume one can find most excellent descriptions of the character of normal respiration, the morbid modifications of the respiratory sounds in pneumonia, pulmonary edema, bronchial catarrh, tuberculosis, etc. Laennec invented the name 'crepitant rale,' which alone would suffice to make his name illustrious. Armed with his stethoscope he diagnosed and named pneumothorax and hydropneumothorax. His clinical and pathological descriptions of the finding in tuberculosis from infiltration to cavity formation will always remain classic. His treatise is an original work which does not resemble any other. All therein is of value, all harmoniously put together by a man who was a lover of 'belles lettres,' an artist, a musician with a wonderfully trained ear, and a sage able to interpret in modern medical phraseology the work of Hippocrates, the father of scientific medicine. The glory of Laennec's works lies in the fact that he utilized his vast knowledge of pathological anatomy in the clinical description of the diseases of the respiratory system."

This is only a fragmentary reproduction in English of Professor Letulle's most eloquent discourse. In laying a wreath of laurels at the foot of the monument of Laennec, he pronounced the following impressive words: "In the name of the Faculty of Medicine of Paris, I bring this tribute to the founder of contemporary medicine as an expression of admiration and profoundest gratitude—to the immortal author of 'Le Traité de l'Auscultation Médiate,' to the teacher of our teachers, eternal glory to Laennec."

If apostolic succession holds good of the clergy, it also holds good of the medical profession. Our Clarks, our Bowditchs, our Flints, our Smiths, our Janeways, and many others of our teachers were also pupils of the pupils of Laennec; and the present generation of American clinicians should be, and I know is, as grateful to have had his teachings transmitted to us as are our French brethren across the sea. Our own Osler, though England claims him now, became enthusiastic in his admiration of Laennec whenever he had a chance to mention his name. His gratitude for what that great French physician did to advance our knowledge of tuberculosis, he tried to instill into his pupils. The Laennec Society for the Study of Tuberculosis is a part of Johns Hopkins Medical School. It was called into life by Osler so that the name of the great phpsician may be perpetuated among American students and be an inspiration to greater efforts in our studies of the disease of all diseases—tuberculosis. By founding this society one of the greatest physicians of our times belonging to the Anglo-Saxon race paid his homage to the immortal French physician, René Théophile Hyacinthe Laennec.

And now that full one hundred years have passed
Since first your great work saw the light of day,
We, of this new land, but lovers of your France,
Would also lay our laurels at your feet,
We, too, our tribute bring, beloved Laennec.
Through ardent labor you enriched our art
When grave disease was hidden from our eyes
Your stethoscope revealed it to the ear
And thus helped countless lives to health and joy,
So to the wreaths of laurels offered you
By your fair France, America adds hers,
A tribute to the master of us all.

16 West Ninety-fifth Street.

A NEW TECHNIQUE IN THE TREATMENT OF CANCER.

By FINLEY R. COOK, M.D.,
NEW YORK.

ALL procedures the prime and sole objective of which has been the removal or destruction of the localized manifestations of cancer have fallen far short of a satisfactory outcome.

While much remains to be learned with regard to the nature and treatment of malignant processes and while presumably this will continue to be true until normal biological phenomena are reducible to their ultimate physico-chemical terms and are interpretable from a simple mechanical basis, certain propositions pertaining thereto are beginning to assume the nature of lucid facts.

In the first place, it is unquestionable that all methods of intervention, whether by surgery, radium, *x*-ray, or other local procedures, as so far evolved or practised, cannot be relied upon in the average, not to mention the extreme case of cancer. It does not necessarily follow, however, because any one measure has failed to meet all exigencies of the situation, that all such are to be wantonly cast aside or abandoned *in toto;* for, contrary to accepted ideas, the progress has evidently been revolutionary rather than solely evolutionary in character; that it is marked by a certain retracement of steps, involution, as well as by a direct forward movement, and the manifold qualitative as well as quantitative variations which characterize the disease may demand a selective synthesis of more than one of the various procedures which clinical experience has demonstrated to possess more or less therapeutic efficacy, besides still others the indications for which are clear and unmistakable.

Secondly, continuity, the basic law governing all biological phenomena, is interpretable from two opposite points of view—Unity and Variation. It is a striking fact that all routine methods of treatment have been based upon the single and hence

one-sided viewpoint of Variation; consequently it must have been apparent at the very outset that all such measures would naturally fall into more or less ill-repute.

As a logical result of this incomplete conception of the disease in which all local stigma assume a positive or dominant and all constitutional stigmata a negative or recessive aspect, the neoplastic factor has been falsely and unbiologically assumed to be a dissociated and therefore isolated feature of the malignant process; the cancer cell so-called to be a malignant cell *per se;* a part to be the whole; and the localized growth to be an exclusive causal entity.

This narrow viewpoint of malignant phenomena, Variation, which follows in passing from causes to results, is the obvious outcome of relying wholly upon the differentiative procedures of pure analysis; for when the mechanical stigmata of malignancy traceable through the structural variations in cell form and mass are simply reversed or synthetized, in the retracement from results to causes, just the opposite viewpoint presents, namely that of Unity; and the neoplasm from its co-ordinative perspective, Unity, irrespective of qualitative or quantitative variations, is an obligatory extension of the somatoplasm and is, therefore, associated with the general organism as a part of the whole; the cancer cell is a variable but, nevertheless, definite morphological variation in continuity with its ancestral prototype; and the resultant structural aberration is the obligatory effect of certain definite, however obscure, changes in the physicochemical processes which dominate normal cell metabolism and which are fundamental in all variations pertaining to structure and function manifest through growth and reproduction.

The third general fact pertaining to the biomechanical nature and treatment of cancer, following in logical order, is a truism. It is self-evident that all changes or variations which obtain in cancer, systemic or local, gross or microscopical, are the natural effects of antecedent physicochemical causes. Whatever theoretical virtue therefore may be surmised to attend the attempted removal of purely local effects, just as the removal of water from a spring-fed pool, or a twig from a growing tree, the mechanical consequence of such procedures would appear, *a priori,* to be an increase rather than a decrease in malignant potentiality.

Mechanically, then, while malignant potentiality must constitute the paramount issue, the general potential energy of position presents two opposite phases; the transformation of dynamic to potential and reversely, the retransformation of potential to dynamic. The former is cumulative and the latter is distributive in a continuity of actions, reactions, and interactions, and hence the rational mechanical or biomechanical treatment of cancer must take cognizance of the intake rather than the output, the cumulative rather than the distributive phase of malignant potentiality relative to its dynamic transformation through aberrant growth and reproduction.

Fourthly, the established methods for the treatment of cancer have been based upon the assumption that effects were causes. Besides the impracticability which has characterized many hypotheses, as, for example, Cohnheim's hypothesis, they are open to the same criticism; in following biological movements from causes to effects, they ignore primary causes and attribute sole causal potencies to resultant phenomena. This is the inevitable outcome when such potencies are fixed upon such factors as local irritations, focal infections, endocrine glands, the autonomous nervous system, or other factors dissociated and isolated within the artificial confines of the organism itself, which invariably overlook the environment and break the lines of adaptive continuity. The only endings of such movements are in vicious circles, which, having been stripped of beginnings as well as of endings, fail to reach ultimate causes.

This ever menacing circle is obviously referable to the general reversibility of causes and effects in virtue of which any given change may be regarded as either a cause or an effect depending wholly upon the point of view; whether correlated with preceding or succeeding physicochemical links in a given chain of biological continuity.

Besides paying no regard to the multitudinous interactions which coordinate the parts with the organism as a whole, such circular movements are in reality only static and for the most part futile positions assumed relative to the physicochemical processes basic to biological phenomena, and stop short therefore of the main objective; the ultimate source of pathogenic potentiality.

Fifthly, it is well established that all biological variations manifested through structure or function, growth or reproduction, are the results of adaptation, and that adaptation comprises all interactions pertaining to the organism and its organic and inorganic environment. Until positive evidence to the contrary can be adduced, it is assumable that malignant variations of biological phenomena conform to this universal law.

It is an important fact that the accepted lines of treatment have been distinguished by their absolute disregard of all environmental factors; routine procedures in the past have utterly failed to take any cognizance of the most fundamental biological law which governs the genesis and evoluton of the phenomenon under treatment.

As between all phenomena, there are certain points of analogy between cancer and tuberculosis. While the mortality from tuberculosis has decreased, that of cancer has either increased or remained *in statu quo.* In the treatment of tuberculosis, clinical experience has demonstrated the practical import of every environmental feature, hygienic and dietic, and psychical as well as physical and chemical. Its rational treatment which rests upon a broad and comprehensive biosociological basis, is noteworthy for the fact that methods of prevention predominate over those of simple remediation.

Although local degenerative cell changes obtain alike in cancer and tuberculosis, the basic principle which underlies the neoplastic phase of cancer, contrary to past teachings, is that of regeneration, not degeneration, and so vitally so as to baffle most measures whose only objective is the direct inducement of degenerative processes.

The concept that the neoplastic phase of cancer stigmatizes degenerative phenomena has served to obscure not only the real nature of such phenomena, but bearings of far greater import, such as the

basic interactions between the systemic and local cell changes and the correlation between its neoplastic and somatoplastic phases, the essence of the problem as a whole.

While degenerative changes necessarily succeed regenerative changes, the two opposed processes are not only reversible but necessarily complementary in any biological continuity. In tuberculosis the regenerative phase is unicellular and hence exogenous and parasitic; in cancer the analogous phase is multicellular and endogenous and although not strictly parasitic in character, the differentiation is only relative; for the neoplasm, as regards its pabulum and other interactions, and particularly in its metastatic phases, progressively simulates a parasitic symbiosis.

This analogy naturally led to the passing conception that cancer itself was the result of the symbiotic interactions between unicellular and multicellular organisms, a proposition which, if true, just as is the case in tuberculosis, would not cause any radical change, either in respect to the character of the process or its treatment; for in both instances the problem would remain a physicochemical one pertaining to predisposition or immunity.

Furthermore, in the tuberculous cycle, the parasitic phase is clearly dependent not only upon its immediate environment, the multicellular host, but equally if more remotely, upon the general environment of organism as a whole. In the malignant cycle, although the same basic biological conditions evidently prevail, no cognizance has been taken of the same, either in theory or in practice. This oversight naturally led to the crumbling belief that the knife was the only cure for cancer; that the removal of effects removed their causes.

Futile attempts were then made to fill the surgical gap, first by means of the *x*-ray, then by radium, perpetuating the same oversight in respect to the etiological bearings of the environment through adaptation. Whatever evidence there is, is otherwise.

In the first place, irrespective of variations, there remains to be found an organism without an environment.

Secondly, the adaptive variations which every organism presents, irrespective of their normalities or abnormalities, in virtue of being the resultants of the interactions between the organism and its environment, involve the environment to which the organism is adapted, as well as the organism which adapts.

But specific facts, as well as general principles, point in the same direction. The frequent recurrence of malignant neoplasms following the most radical excisions; the outcropping of the same at the site of previously removed growths distinctly benign, the removal of which has been part of a local and narrow propaganda; the tendency to metastasize; the spontaneous cure of cancer, an event in all likelihood, as in the case of tuberculosis, more common than is demonstrable by local clinical signs; the correlation between the age incidence and that which marks the natural biological reversion in the somatic cycle; the hereditary predisposition to the disease in certain family strains; the full import of which, in virtue of the recessive nature of such potencies, is presumably underrated; fluctuations in growth energy, marked by periods of acceleration or retardation, remission or regression; the evidence of constitutional immunity, relative or absolute, established by experimentation in lower animal types, are all more or less indicative of potential forces located beyond the immediate confines of the malignant mass.

Sixthly, cancer is a disease of general metabolism. All biological changes in general are dependent upon metabolic actions, reactions, and interactions. All structural and functional variations are resultant upon the give and take between the cell and its environment; upon the up-building and down-tearing, the physicochemical associative and dissociative processes of general protoplastic syntheses and are analyses, or anabolism and catabolism.

Deductively, therefore, malignant changes are essentially metabolic in character. Inductively, the syndrome of cancer presents a picture painted in striking metabolic hues; a marked change in the normal relativity between constructive and destructive phenomena.

Systemically, the loss in mass, in weight, in form extension, and in general protoplastic potential evidence the predominance of catabolism over anabolism. Locally, the gain in mass, in weight, in form extension, and in neoplastic potential evidence the predominance of anabolism over catabolism. These structural and functional variations which stigmatize the systemic changes on the one hand, and the local on the other, as involutory and evolutory movements respectively, are not only the direct effects of physicochemical or metabolic processes, but doubtlessly offer the most important clue to the nature and cure of cancer.

Lastly, the synthetic viewpoint of cancer logically leads to the seventh apparent and doubtlessly the most important fact respecting its ultimate physicochemical nature and treatment. Just as biomechanical continuity, manifest through structural and functional variations, is maintained only through adaptation, and just as adaptation is dependent upon metabolism, so metabolism itself, in virtue of involving the various processes of nutrition, is utterly impossible without those special elements which constitute the natural food products.

As it is certain that all centers of growth, irrespective of quality or quantity, are dependent upon appropriate surrounding media for their growth energy, and as it is no less certain that such energy is derived from the analysis and synthesis of food products, it is assumable upon general biological principles alone, that the potential energy manifest dynamically through malignant growth is a natural product of the dietetic adaptation of the general organism.

While the import of dietetic adaptations under the constantly varying conditions of life, the most important of which may be summarized as age, occupation, climate, ratio of mental and physical work to rest, and constitutional idiosyncrasies, is beginning to receive more attention from a general etiological point of view, and while, theoretically at least, it would seem impossible to conceive of any structural or functional departure from normal standards which did not involve those food elements basic to metabolic phenomena, even in those diseases involving a definite parasitic symbiosis, where the

environment is a *sine qua non*, the problems bearing upon the relationship of food-intake to malignant output have been more or less ignored.

Unfortunately positive data bearing upon this vital question are not only scant but conflicting. At one extreme, current opinions, particularly those emanating from ultrasurgical sources, have been decidedly opposed to any concept of nutritive affiliations in connection with malignant growths; at the other extreme, nearly every article in the dietary of man has been proclaimed to be the one and only cause of cancer.

Besides those factors of a general nature which pertain to the simple basic or mechanical interpretation of the energy conservations and transformations involved in pathological phenomena, and their correlations with the fundamental principles which govern all biological adaptations, there are specific reasons for the tardy recognition of malignant phenomena from their natural environmental point of view, in which nutrition certainly constitutes the chief adaptive factor.

1. The two predominating signs or effects of cancer are general emaciation and local growth. Both effects are the results of an unstabilized nutrition; the former of hyponutritive, and the latter of hypernutritive physicochemical processes. One of the most striking clinical features of the disease, however, is its presence in individuals who have not only been comparatively free from other diseases, but who have been more or less distinguished for either physical or mental capacity and endurance.

2. The relative infrequency of cancer at the extremes of life, as well as its rare occurrence under those impoverished conditions which follow acute affections, when general potential is below an optimum, does not point to hyponutrition or undernourishment as a primary predisposing factor. On the contrary, it may reasonably be inferred from these facts, together with the foregoing, that other diseases as distributive phases of energy act as safety-valves, as regards the genesis of cancer, and that metabolic changes of a reverse cycle may precede the cycle the clinical signs of which are at present recognized as marking its clinical onset.

Moreover, the fact that patients presenting such signs commonly give a history of having been overweight in conjunction with other stigmata of an unbalanced metabolism, would tend to support the same assumption, namely, that the real origin of cancer is at present not recognized as such.

3. The natural recourse to such dietary procedures as are more or less effective under conditions of general inanition from other sources, have proved notably ineffective in arresting or retarding either the constitutional retrogressive or the local progressive changes in cancer, and this fact, perhaps more than any other, has led to the insidious but fatuous and unbiological dissociation of the disease from its natural biophysical and biochemical affiliations with the physichochemical processes which dominate general metabolism.

4. Owing chiefly to the multiplicity of factors, such as age, climate, heredity, occupation, as well as food products, which influence metabolism, in virtue of which any specific variation in one is subject to those en masse, general statistical deductions, particularly those based upon geographical differentiations as well as those adduced from animal experimentation, have served to befog rather than to clarify the etiological import of nutritional processes.

5. The influence of local trauma or irritation, as being a more patent and direct exciting cause in many, if not in all cases, has led to the overvaluation of a supposedly local at the expense of other constitutional factors. Besides the fact that such phenomena are localizing factors in many other diseases, the complexity as well as variability of such tissue reactions show that they cannot be regarded in the light of purely local phenomena.

On the other hand, as these resultant changes are adaptive in character, they are dependent upon the physicochemical status of general metabolism, or upon the lability, resistance, or immunity of the organism as a whole.

Treatment.—In January, 1916, we began to use a modified technique in the treatment of cancer. This treatment was based upon a biomechanical hypothesis. The measures employed, in brief, were a combination of certain dietetic and Roentgenotherapeutic procedures with a twofold objective. The prime object was to induce gradual regressive changes in the neoplasm, indirectly and spontaneously, through radical changes in general metabolism.

A second one was to avoid any direct destructive or hyperreaction upon malignant cells, in order to escape the results which usually attend such procedures, namely, secondary stimulation of primary lesions and general metastases.

The dietary was aimed to break the continuity of malignant adaptation through assimilation, and the radiations to combat a cumulative action through elimination, the former to reach the dynamic intake, and the latter the dynamic output of malignant potentiality.

The results showed a marked improvement on those previously obtained when relying wholly upon either local or systemic radiations and from the evidence at hand it would seem reasonable to assume that these results were due to the combination of preventive and remedial influences referable to certain dietetic and radioactive procedures respectively.

In no single instance among thirty extreme cases, recurrent or inoperable, all of which had been pronounced hopeless by competent specialists, was there a failure to secure either a marked improvement or a radical cure. In a number of operable cases, some of which were recurrent after a primary excision, there was a successful outcome in every case.

Dietetic Regime.—The dietary comprised the following procedures:

1. The strict exclusion of animal food products, such as meat, eggs, milk and cheese, and all mixed foods which contain the same.

2. The reduction in the amount of vegetable products rich in proteins, such as peas, beans and nuts, in accordance with variations in the systolic and dyastolic blood-pressures.

3. The regulation of fats and carbohydrates, mainly in accordance with variations in weight.

4. The liberal allowance of fruits and green vegetables.

This regime, the three basic principles of which may be summarized as decrease of proteins to a minimum, increase of basic elements to a maximum, and adjustment of hydrocarbons to an optimum, were founded upon the following clinical observations and general biomechanical principles:

1. All biological research, since the classic work of Atwater, has fully demonstrated the mechanical nature of metabolic phenomena. Mechanically the restablishment of a stabile equilibrium in general metabolism calls for a reversion in extremes, rather than a balanced ration, in respect to adaptive nutritive factors.

2. Whatever deductions may be drawn pertaining to the hypothetical nature of cancer, it is certain that its localized manifestation is a phenomenon of growth and that nitrogen is the element par excellence in all growth phenomena.

3. The biochemical explorations of Kocher, Osborn and Mendal, Sweet and Rous, and many others have demonstrated the import of nitrogenous metabolism in malignant transmutations. Kocher found that the amino-acid content of malignant neoplastic cells was roughly double that of normal somatic cells. Osborn and Mendal demonstrated the inhibitory action of withdrawing certain protein products on both somatic and neoplastic growth. Sweet and Rous showed that the tendency to metastasize in carcinomatous rats was diminished on a diet deficient in certain basic amino-acids.

4. It has been our personal experience that a careful analysis of the dietetic habits of patients presenting the stigmata of malignancy invariably reveals an habituation to regimens characterized by a highly nitrogenous and hence unbalanced intake; that although an aversion for such food products is sooner or later acquired, contrary to instincts, but in compliance with a common practice, it is customary to increase the animal proteins, particularly eggs and milk, to check the progressive loss in weight, which not infrequently precedes the appearance of local signs; and, moreover, a fact of paramount import, that it is possible to observe an actual and at times marked increase in malignant growth processes, especially when such products have been forced or resumed after a period of abstinence.

5. Cancer is commonly associated with a relatively high arterial pressure, even in its terminal phases, and it is not only well known that hypertension states are referable to dietaries characterized on the one hand by an excess of nitrogenous products, and on the other by a paucity of basic salts, but that no material reduction in tension can be maintained without a reversion with respect to these dietary elements. And in conjunction with this phase of the subject it is important to take cognizance of the facts that (*a*) the accepted standards of pressure normality, wrongly based as they were upon averages, are in all likelihood, from twenty to forty millimetres too high; (*b*) the early estimations of minimal protein needs established by Voit and Atwater, having been confused with vitamine requirements, have been progessively reduced by subsequent investigations; and (*c*) a large and apparently increasing number of individuals become sensitized to animal proteins and are able to maintain a normal pressure and metabolism only by their more or less strict exclusion.

6. Cancer is also associated with sedentary habits, particularly so when suddenly enforced on persons not adjusted or constitutionally adapted to the same, and it is under such physical conditions, especially when accompanied with mental stress or strain, at the cancer age incidence, when the organism is beginning to wane in its adaptability to environmental changes and has passed the maximum in growth and development, when such growth-producing products as meat, eggs, and milk are apt to engender perverted states in general metabolism accompanied by hypertension and other stigmata indicative of a presenile degeneration or involution of the organism as a whole.

7. Various reasons may be cited for the apparent necessity of regulating the carbohydrates in the dietotherapy of cancer; animal experimentation has shown that a reduction in carbohydrates as well as in proteins tends to retard malignant growth; it is well established that the carbohydrates are protein savers, and tend to retard nitrogenous metabolism; that a reduction in carbohydrates, especially under conditions of overweight, tends to accelerate metabolism, not only directly by their decrease, but indirectly by the relative increase in the mineral constituents of a balanced dietary.

X-ray Treatment.—Our technique and objective are largely the direct reverse of those heretofore employed in the treatment of cancer. Instead of a limited number of local maximal reactions in a minimum of time, we substituted an unlimited number of minimal systemic reactions in a maximum of time, both as regards individual treatments and the treatment as a whole.

Although it is well established that radioreactions are both systemic and local in character, these systemic potencies have been strangely disregarded in the radiotherapeutic treatment of cancer. Although local radiations are invariably accompanied by systemic reactions, and systemic radiations by local reactions, the differentiation, like all such differentiations, is necessarily one of relativity, and the differentiative factors are largely those pertaining to the position of the tube in relation to the local lesion, whether the latter is included or excluded in respect to the radiofield, changes in the position of the tube, target distance, and to the character of the radiations, whether continuous or intermittent.

The fact that various local changes in cell structure and function are induced in distant parts of the body under local exposures, as well as the fact that local regressive changes in malignant neoplasms may be induced by systemic exposures, in spite of all measures taken to isolate the local lesion from the direct field of action, demonstrate systemic effects in either case.

The investigations of Murphy and others were decidedly opposed to the common concept that the *x*-rays have any direct and local destructive action upon malignant cells. In the mouse experiments of Murphy, local regressive changes in malignant tumors were found to be invariably associated with systemic reactions characterized by a numerical increase in lymphocytes and by an acceleration in phagocytosis.

Chemically systemic radioreactions have been found to be correlated with physicochemical changes in general metabolism and to involve the protein content of general cell structure, evidenced by an increased output of urinary nitrogen and by an increase in the nonprotein nitrogen of the blood.

Edsal and Pemberton, who studied the general toxic effects of massive *x*-ray doses, attributed these effects to an acceleration in protein catabolism, and the well-known influence of radiotherapy in eczema, psoriasis, rheumatoid affections, and other disorders of general metabolism associated with a high arterial tension, acid diathesis, and nitrogen metabolism, taken in conjunction with its recognized influence upon malignant processes, is further evidence of the etiological rôle played by the element nitrogen in the metabolic derangements incident to cancer. Changes in pulse-rate, blood-count, blood-pressure, weight, oxidation, osmosis, secretions and excretions, evidence the fact that *x*-rays exert a profound influence upon general metabolism, and cumulative evidence shows that this influence, under unbalanced metabolic conditions, is one of stabilization through reversions in respect to the two opposed processes, synthetic and analytic, which dominate protoplastic phenomena.

The fact that in the usual pursuance of the exclusive *x*-ray treatment of cancer a point is sooner or later reached where a direct reversion is evident in radioreactions, and beyond which point the only effect of further treatment is the acceleration of the malignant process, is striking proof of the general limitations of the exclusive treatment of the disease by means of the Röentgen rays, as well as of radical mechanical errors in radiotechnique.

The frequent recurrence of the local phenomena of cancer after their apparent complete regression in response to Röentgenization, radiumization, or even after a radical excision, where no attempt is made to alter the environmental conditions under which such local effects have evolved, points to the wisdom as well as the necessity of resorting to measures of a more constitutional or preventive character. The current idea that small local doses stimulate and large ones destroy malignant cells, is in common with all biomechanical generalizations, subject to manifold exceptions or reversions. Assuming a biological impossibility, an equal resistance in any given grouping of cells, the proposition is apparently true within certain limitations; particularly so in those small-cell groups which characterize superficial malignancy. Moreover the clinical results in such instances are known to follow changes that are constructive not destructive, and in cells normal not malignant. Furthermore there are three rather than two immediate reactive cell phases, for whereas, the ultimate effects are either constructive or destructive, minimal doses are sedative or retardative.

Still other factors complicate the situation when dealing with the deeply seated types, and tend to negative any possible destructive potency of local massive doses:

1. It is impossible to exclude all nonmalignant and possibly premalignant cells from any relatively localized radiofield.

2. It is well established that *x*-rays, and particularly through their cumulative action, transmute normal to malignant cells; this potency is naturally enhanced by a constitutional predisposition to malignancy, which all clinical situations presumably involve.

3. The reactivity and resistance of malignant cells vary, not only in different malignant types and in different instances of the same type, but also in the different planes which characterize the field of action in every instance of all types.

4. While the resultants of the interactions between active and reactive forces are reciprocally dependent upon both, the resistance of any individual cell group, in a multicelllular organism structurally and functionally differentiated and coordinated, is furthermore dependent upon the general status or resistance of the organism as a whole.

5. As the resultant changes induced by radiation are systemic as well as local, the relativity of which is subject to an infinite number of variations through qualitative and quantitative adjustments in technique, this relativity is an important factor in all local reactions and hence in ultimate clinical results.

6. Local reactions are influenced by many constitutional factors which link the organism to its environment through adaptation, the most important of which pertain to processes of assimilation and nutrition. The immediate effects of radiation, as shown by changes in weight, blood-pressure, and in the excreta, are primarily dissociative, catabolic and eliminative in character.

In destructive cell changes these reactions are compensated by regenerative phenomena in environing cells. In constructive cell changes these same reactions, reduced as to intensity and duration, are compensated by a subsequent reversion in the same cells characterized by an acceleration in assimilation and anabolism.

Malignant growths have doubtless regressed in response to local massive and apparently exclusive *x*-ray procedures, particularly the superficial epithelial types, but the evidence at hand, histological as well as clinical, shows that these results are traceable indirectly to nutritive rather than directly to destructive processes.

The various types of hyperemia, varying from a transient active to a persistent passive hyperemia, as well as the proliferative and obliterative changes in vessel walls and lumens inducible by radiation, involving both qualitative and quantitative changes in the nutrient blood-stream, are evidently correlated with the processes of malignant cell nutrition. Hyperreactions, the cumulative effects of repeated local radiations, manifest by a passive hyperemia or venous congestion with its concomitant lymphatic stasis, activate the local malignant process; both regressive and progressive changes appear in a common malignant field; the former has commonly led to a false optimism, and the latter to an increase in dosage, the usual result of which has been an acceleration of the disease as a whole.

Effects of Treatment.—The effects of this combination treatment are both systemic and local. Systemically, the immediate changes are those pertaining to pulse-rate, blood-pressure, and general capillary circulation, and in the urinary output. The pulse is generally retarded, the systolic and

diastolic pressures are instantly lowered, the reciprocal pressure tends to approximate a normal ratio, and there is an increase in the catabolism of urea and uric acid. If the dietary adjustments, however, have proceded the application of the *x*-rays the urinary output of these products may fall to or below the normal.

The remote effects consist in a marked improvement in the patient's mental and physical condition, in the removal of achexia, and in a progressive loss in weight. The loss in weight accompanies the fall in pressure and in the reduction in local and general edemas; it takes place more rapidly than the usual pace under such conditions and in favorable cases it proceeds to a certain point which apparently marks the end of a catabolic cycle and is then followed by a gradual gain in weight. Following this cycle and with few exceptions there is a real desire for food which is rare in malignant cases and it accompanies an improvement in general secretary functioning which is secondary to the cycle of elimination.

A sudden rise in the systolic pressure during the catabolic cycle, other factors having been eliminated, is the result of errors in dietetic balancing, an excess in the protein content; it closely parallels an increase in weight.

A fall in all three pressures, particularly the reciprocal, below normal, accompanied by a sudden gain in weight, is usually significant of either an excess in carbohydrates or a deficiency in proteins or basic salts, or of these factors in combination.

Locally, immediate but slight changes are invariably discernible within and environing the neoplasm after the first systemic radiation. The local lesion is contracted, is softer, its surface tension is lowered, and the peripheral edema is reduced. These effects are obviously the result of changes in general osmosis, for they are concomitant with similar changes in distal edemas when present, and also with alterations in the general circulation as indicated by blood-pressure notations. More remotely and from time to time characteristic reactions take place within and surrounding the primary lesion. These reactions are characterized by a temporary increase in mass, in surface heat, and in sensitiveness on pressure, and by a more rounded contour; but following such reactions there is a more or less reduction in the tumor mass.

THE CHRISTIAN SCIENCE PSYCHOSIS.

By EDWARD HUNTINGTON WILLIAMS, M.D.,

LOS ANGELES, CAL.

THE term "Christian Science Psychosis" is used here to designate a definite type of mental aberration, not as an implication that all persons afflicted with this peculiar latter-day obliquity are suffering from a psychosis. Indeed, there are at least four other types of persons belonging to this cult who can not be classed as truly psychotic. Thus, there are:

1. Persons who do not attempt to fathom the vagaries of Mother Eddy's ambiguous volume, but who feel the need of some religious uplift;

2. Persons with a pecuniary turn of mind, who may or may not have any very deep convictions about religious subjects, but who sense the possibility of some profit in getting aboard this religio-medical excursion train;

3. Earnest persons, who read and reread their "Science and Health;" and having read and reread, believe that they think they understand the entirely incomprehensible sentences—the squint-brained type of individuals, frequently cultured and apparently intelligent, who are congenital faddists and whose particular fad for the moment is Christian Science; and,

4. Persons with an incurable affliction who, having tried every thing else without benefit, seize upon this last straw with entirely pardonable avidity, and frequently most comforting results.

None of the individuals in any of these four groups are necessarily actually psychopaths, although frequently somewhat wabbly in mental equilibrium. But there is a fifth group who develop a true psychosis the symptoms of which are those of a mild religious ecstasy somewhat different from the ordinary type of religious aberration and, indeed, a little at variance with the conditions usually observed in this class of cases.

Needless to say these persons are of the emotional, neurotic type, and almost without exception, women. Frequently they are capable and attractive. But their mental abnormality shows itself in a kind of dual personality in which they live the combination of ordinary mundane life and an "ethereal" one which constantly obtrudes itself.

The following cases are illustrative:

CASE I.—Mrs. M., age forty, the eldest of three children. Both parents were highly intelligent and cultured persons; and both of the patient's sisters are somewhat neurotic. Patient herself has always been nervous and emotional, but there is no history of severe illness in childhood and her development was uneventful and normal. Married at twenty-one, and two years later gave birth to her only child who is now an exceptionally bright and well-balanced young man. Eight years after marriage developed insipient pulmonary tuberculosis, but two years later had entirely recovered, and at the present presents no symptoms of the infection. Immediately following the tuberculous infection, however, she developed distinctly neurasthenic symptoms characterized by marked claustrophobia. Thus, she frequently found it impossible to attend the theater because she imagined the crowd about her suffocated her, and in general she found it difficult to go into crowded enclosures of any kind. Her phobia was always that of suffocation. As a result she became something of a recluse, introspective and mildly depressed, although always a good housekeeper and good mother. Her family life was normal and she was happily married, not merely in the Christian Science sense, but actually so. Her husband, who is a sympathetic but unusually level-headed business man, was indulgent but not overly so. There was really nothing to worry her either in financial or family matters except her own delusions. But these continued for a period of about five years. Then she was caught in the Christian Science wave and began reading Mrs. Eddy's book and attending Christian Science meetings. Almost immediately her claustrophobic obsession vanished—was transmuted, if you please, into a "Science and Health" ecstasy. She read, and talked, and thought practically nothing else; yet always attending to her domestic duties and household affairs in a fairly effective manner. This work was, of course, of the more or less mechanical character which required very little or no mental concentration. Thus her mind was left practically untrammeled to soar upward into the ethereal altitudes of the Mother Church regardless of the mechanical task in hand.

When one engaged her in conversation upon any

topic this peculiar exotic state was always noticeable. And although she answered questions intelligently and carried on a fairly good conversation, there was only a half-concentration on what she was saying. Meanwhile her "higher thoughts" were cavorting in the hazy clouds of unreality.

When she undertakes some particularly adventuresome task, such as paying a visit to a distant part of the city, she takes her "Science and Health" with her, Baedeker fashion. And although she seldom reads the volume in public, she constantly fortifies herself by repeating passages from the inspired pages while in transit. Her condition has remained practically unchanged for at least four years.

CASE II.—Mrs. B., 33 years old, married, no children. Her father was a very erratic man, her mother one of those colorless, "neutral" sort of individuals. The patient has one sister two years older than herself who is suffering from dementia praecox. The patient herself gives the history of having a "nervous breakdown" ten years ago and from what I can learn this breakdown consisted of an attack of actual insanity which lasted something like a year. Her domestic relations had not been entirely harmonious for some time before this; and shortly after her recovery she took the plunge into Christian Science—presumably as a kind of substitute felicity. And if one may believe her statements, the plunge has proved a veritable panacea, dispelling all her troubles, mental, moral, and physical. But what she really has is a mild exaltation, very similar to the case just described, but somewhat more marked to casual observation. In her case the "far away" expression is scarcely disguised at any time. It is quite impossible to fix her attention completely in conversation, even when the topic is of utmost importance to her. Yet she responds constantly to questions and even interjects such exclamations as "How delightful," or "Oh, isn't that splendid," at the proper time and place. Meanwhile you are fully aware, however, that her mind is not really centered upon the "splendid," and "delightful" things to which you have referred, but is rambling aimlessly about in the pink tinted clouds of the Christian Science firmament. She is in a sort of dream state, and she never gets out of it.

CASE III.—Mrs. S., 32 years old. Patient was an apparently healthy and normal girl, happily married at twenty-one, and two years later gave birth to her only child. She was always a high strung, "temperamental" individual somewhat inclined to be over zealous in her solicitude about the welfare of others. Was deeply interested in religious topics, and three years ago took up Christian Science. After a few months she developed an exalted mental condition very similar to that of the two cases just described, and continued in this condition for a matter of four or five months. Then her condition rather suddenly became still further exalted to such an extent that she neglected her domestic affairs, began having open and sometimes boisterous communications with imaginary persons, which necessitated her confinement in an institution. This was a little over one year ago and at the present time she is still in the institution. She is somewhat quieter and less demonstrative than formerly, and at times shows a certain apathy or mild depression.

It will be noted that these cases are closely similar to some other forms of psychoses in which religious delusions predominate, except that the element of fear is almost wholly wanting. And this is explained, I think, by the fact that "fear" and "punishment" are eliminated in Christian Science teachings. Thus the psychotic Christian Scientist exemplifies the "adaptability" of insane delusions and hallucinations.

We see this adaptability illustrated in other forms of insanity in the various types of hallucinations about electricity. At present an imaginary wireless influence is the popular one. Twenty-five years ago, before the days of wireless telegraphy, it was wire-conducted electricity that played havoc with the asylum inmates. Prior to the period of applied electricity the influence of "evil eye" and "thought-transference" were in the spot light of aberrant mental conditions. And going back a little further (and not so very far, at that) we have the influence of demons and devils and varied forms of disreputable spirits, whose long period of popularity has been eclipsed, although by no means suppressed, by the advent of applied electricity with its endless variety of mysterious devices.

So with religious delusions. For the last century our interpretation of religion has been taking on a much less fearsome aspect. Satan as a personality has been suppressed to such an extent that he is no longer a dominant figure in most religious teachings. Yet in many abnormal mental syndromes of a religious character we still find evidence of his obtrusions in the element of fear. And in this respect there is a difference between the Christian Science psychosis and the older form of religious aberration.

The explanation is obvious—the suggestion of fear and future punishment is wanting in Mrs. Eddy's vagrom teachings. Throughout the entire category of mystic and mysterious ramblings of "Science and Health" there is pre-eminently hope and love, and practically no suggestions of fear or punishment.

Thus, when the Christian Scientist's balance wheel goes askew (and frequently it hasn't very far to go) he is not distracted by the fear of molten punishment, as is frequently the case with the old fashioned orthodox Christian. There isn't any hell in the Christian Science lexicon, and therefore one need not be bothered by what does not exist. In this respect, then, the Christian Science psychosis has an advantage over the older form—it is at least a happier form of dementia.

In this connection it is interesting to note that, despite the obviously contradictory attitude of such an admission, the author of "Science and Health" admits the existence of insanity and offers a remedy. This is Mrs. Eddy's suggestion for treatment:

> The treatment of insanity is especially interesting. However obstinate the case, it yields more readily than do most diseases to the salutary action of truth, which counteracts error. The arguments to be used in curing insanity are the same as in other diseases: namely, the impossibility that matter, brain, can control or derange mind, can suffer or cause suffering; also the fact that truth and love will establish a healthy state, guide and govern mortal mind or the thought of the patient, and destroy all error, whether it is called dementia, hatred, or any other discord.
>
> To fix truth steadfastly in your patients' thoughts, explain Christian Science to them, but not too soon,—not until your patients are prepared for the explanation,—lest you array the sick against their own interests by troubling and perplexing their thought. The Christian Scientist's argument rests on the Christianly scientific basis of being. The Scripture declares, "The Lord He is God (good); there is none else beside Him." Even so, harmony is universal, and discord is unreal. Christian Science declares that Mind is substance, also the matter neither feels, suffers, nor enjoys. Hold these points strongly in view. Keep in mind the verity of being,—that man is the image and likeness of God, in whom all being is painless and permanent. Remember that man's perfection is real and unimpeachable, whereas imperfection is blameworthy, unreal, and is not brought about by divine Love.

All of which leads one to suspect that, whatever the extent of Mrs. Eddy's experience in treating other diseases, her experience with the insane was somewhat limited.

THE PROPOSED COMPULSORY HEALTH INSURANCE LAW.

ITS INJUSTICE TO PHYSICIANS, DENTISTS, AND PHARMACISTS.

By JOHN JOSEPH KINDRED, M.D., LL.B.,

RIVER CREST, ASTORIA, L. I., N. Y.

The bill, providing for compulsory health insurance for employees, that passed the New York Senate at its last session (introduced into the Senate by Senator Davenport, and into the Assembly by Assemblyman Donahue), was first introduced into the Senate by Senator Ogden Mills in 1916, and has since that time been periodically under consideration by the Senate and Assembly through their respective committees on public health. For two years past there have been a number of hearings on this bill, so unjust to physicians, dentists, and pharmacists, and much opposition was developed to it on the part of representatives of the New York State and local county medical societies, because of its obvious class discrimination and other objectionable features.

Physicians have not, in the main, opposed the bill on any other ground than that of unjust discrimination; they certainly have not opposed it because of any hostility to the humane and progressive principles of the proposed law (physicians, above all, as is well known, gladly champion and support all measures for the good of humanity and society), but solely because of the ill-considered and unjust provisions mentioned and to be pointed out and referred to in more detail. In this connection it is significant that the medical societies of the States of Pennsylvania and Iowa have already gone on record as favoring laws similar to the proposed New York State law, but with provisions that are just to physicians in the matter of their hard-earned fees.

There is no class of workers, professional or otherwise, who admittedly work so hard and receive so little in the way of monetary compensation as physicians. So true is this that statistics show that the average general practitioner of medicine and surgery wears himself or herself out at a much earlier age than does the average man or woman in other professions or vocations, and after such sacrifice accumulates little or no property.

Governor Smith sent the Legislature at its last session an emergency message advocating this measure, and, as stated, it passed the Senate. It will be introduced into the present session of the Legislature, and has a good chance to be reported out of the committees and of passing both branches, if its opponents do not immediately organize on an effective basis.

This measure is advocated by the New York State branch of the American Federation of Labor, whose influence as a practical factor is well known, and is fortified by the nearly one million votes (including the added votes of women) controlled by this organization. A careful study of the bill may show an intention on the part of the labor and political leaders, who framed it, to be fair, from their viewpoint, with employers of labor as well as with the officials created under the bill, excepting the physicians, dentists, and pharmacists, who constitute the most necessary part of the machinery for the carrying out of the measure. The employers of the classes of employees protected by the bill (practically all classes of labor except servants, farm laborers, and officers of companies) very naturally object to the immense burden to be placed upon them—50 per cent. of the estimated fifteen to twenty million dollars annually required to pay each employee and members of his family a sick and death benefit, as well as hospital, dental, and druggists' fees for the worker, and also obstetrical expenses, including maternity fees for mothers of these classes, etc.

Dr. S. S. Goldwater, with his usual clearness and thoroughness, in an able article on this subject in the Medical Record of March 8, 1919, discusses the bill impartially, and estimates the cost annually, for each million employees, at about twenty-one million dollars, as compared with the fifteen million dollars claimed by the supporters of the Davenport-Donahue bill. This and other considerations show how experimental and indefinite the proposed measure is as to its actual workings and the cost of carrying out its provisions. These amounts are the estimated costs of the health and death benefits to be provided equally by the employer and the employee, and do not cover the cost of administration of the proposed law (including the salaries and expenses of the commissioners and various bureaus and officials provided for by the bill), which cost is to be met by the State. In this connection comes one of the chief objections by the physicians of the State, and that is that the physicians individually and collectively will be, in the practice of their profession, under the political control of professional politicians who know little and care less for the honor and dignity of the medical profession, and of its ancient and high traditions. In other words, both the high and the petty officials of the proposed political commission could "manipulate" to the advantage of the purely political doctor, so that he would get more than his proportion of practice among this large industrial class, which provides the chief income of the majority of physicians. It is true that under the bill the employees are left free to apply to any licensed physician they may choose whose name is on the "panel of physicians," that is to say, the list of physicians who may hand their names to the commission for this work. But it may easily happen under the workings of the measure, as it is alleged to have happened under the workings of the existing Workman's Compensation Law, with a similar provision allowing an employee to call in any physician of his choice whose name was on the "panel of physicians," that one physician has made over seventy thousand dollars annually, *while most physicians make nothing under this law, and the average physician is rarely, if ever, called in in cases coming under this law.* It is estimated that ten thousand physicians out of the fifteen thousand in New York State are interested largely in industrial practice, that is, their practice consists largely of employees; if these ten thousand

physicians handed in their names for the "panel of physicians," as provided for in the law, they would of course become an important part of this machinery, and they would in such case be compelled to accept such fees as might be fixed by the commissioners or by the head of the bureau (who shall be a physician, but who will in the natural order of things be a political doctor) who is to fix all the medical, surgical, and obstetrical fees after consultation with the local medical societies of each county in the State.

It is provided, however, that, in case of a failure by the medical societies and the head of the bureau to agree on fees, the matter shall be heard by the commissioners, and if they are still in disagreement the matter of fees shall be finally settled by an arbitration board consisting of one representative chosen by the employers of the State, one chosen by the employees, two chosen by the medical society of the State, and a fifth chosen by the Governor of the State.

While it is estimated by some that the basis of the whole annual sum (approximately fifteen to twenty million dollars) to cover health insurance and death benefits for the estimated number of employees of the State is, as it relates to medical fees, about one dollar for visits, fifty cents for office calls, and an obstetrical fee of ten dollars—not at all commensurate with the high cost of living, and away below the regular average fees, it is estimated by others that the average number of calls that each physician *might make*, would be something like 3,400 annually (which would mean an average income of about $3,400 for each of the ten thousand physicians who would make up the medical machinery, *provided that each physician got his pro rata share.* But would he? This last-named estimate is denied by most physicians, informed as to all the varied data to be considered in this vast experiment of a compulsory State health insurance bill, who reckon that the average income of the physician would be only about $1,500 annually.

These guesses are based not only on the whole sum already mentioned, to be contributed on a fifty-fifty basis by the employer and employee (and it is estimated that this sum would not burden either the employer or the employee more than twelve dollars yearly for each employee), but it is also based on the guess that there would be a maximum period of illness annually for each employee, of nine days. Obviously many other expenses have to come out of this whole sum annually, and the practical question is that, with the political administration of this fund, what amount will be left available to pay the physicians, dentists, and pharmacists if they work under this experimental law? The not unnatural assumption is that large overhead expenses will first have to be met, and the doctors will have to take what remains, if anything. Moreover, assuming there is in theory a desire to deal honestly with the physicians, without whose cooperation the measure is bound to fail, their fees should not be conditioned on any uncertainty or theory, but should be fixed, and moreover should be commensurate with their value to society and with the present cost of living. How can this be denied?

I indorse the forceful argument of Dr. John J. O'Reilly, chairman of the Public Health Committee of the Professional Guild of Kings County *in so far as it condemns the injustice of the bill to physicians, dentists, and pharmacists.* His argument clearly sets forth the views of opponents of the bill, who do not see in any of its provisions either sound economics, social betterment, or other benefits claimed for it by its proponents. Dr. O'Reilly says in part:

The only basis for the computation of any form of insurance is the law of averages; if the framers of the Davenport-Donahue Compulsory Health Insurance Bill, used any other basis they were wrong from the start. If they did use this basis (and they claim they did) they must be judged by the law of averages and of the great high priest of that law—the statistician, who says: There are 4,000,000 workmen in the State of New York. The average workman loses nine days each year through illness and his average daily wage is $2.00 and the average annual wage loss is $18.00 or 3.25 per cent. of his annual wage of $554.00 for the 227 working days. That by making the average premium for compulsory health insurance $18.00, and compelling the workman to pay one-half ($9.00), and compelling his employer to pay the other one-half ($9.00), it will be possible to pay the workman cash benefits at the rate of $8.00 per week (of seven days), or $1.14 per day and, in addition, provide him with all necessary medical, surgical, dental, nursing, and specialist's care; medicines and supplies; all hospital care, all laboratory aids; as well as cash benefits for his wife, for the two weeks before and six weeks after her confinement, together with the necessary medical and obstetrical care and supplies. This is very alluring to the gullible workingman and, if practicable, would solve society's most troublous problem and advance the millennium several hundred years. There are several obstacles in the way; one is the mathematical law which says that when you give the average man his nine days cash benefits at $1.14 per day, it makes a total of $10.46 and when you deduct from this the total premium of $18.00 you have a balance of only $7.74 which must be made sufficient to compensate the doctor, the nurses, the druggist; the hospitals, laboratories, and dispensaries; the medical and surgical supply dealers, the dentist and the dental supply dealers; the specialists along various lines, and, in addition to this, to compensate the doctor or the obstetrical specialists (or both) and to furnish all necessary obstetrical supplies, and further, to give the wife of the employee cash benefits of not more than $8.00 per week ($1.14 per day) for a period of two weeks before and six weeks after her confinement, and funeral benefits of $100. Since this leaves a balance of $3.52, the amount available for medical care, etc., is at the rate of only thirty cents (30c.) per day, which surely looks like a lot of work and material for a small amount of money. It sounds absurd; it *is* absurd and its very absurdity should make the citizens of the State of New York extremely suspicious of the prineiple upon which compulsory health insurance of the Davenport-Donahue type is formulated, or wary of the application of that principle which fails to embrace the fact that this compulsory health insurance differs from life, fire, or even voluntary health insurance wherein certain requirements are exacted, such as physical examination or compliance with the rules of the board of fire underwriters, and where the probability of lapses reduces the element of risk—for in this compulsory health insurance there is to be no physical examination, and there can be no lapses because your employer must deduct your share of the premium from your pay envelope and the employer must pay his share or become a misdemeanant and be jailed or fined or both.

The proponents say the insurance will cost the State nothing. Let us see. How is this double-headed premium of $18.00 to be collected and disbursed? By and through whom? How are they to be compensated? The bill provides for the organization of a number of "local trade and establishment funds, each of which shall have a board of directors of seven (7) members and

each of these members shall receive five dollars per day when they attend meetings," and if they attend but one meeting in each of the fifty-two weeks in the year, the total expense for this part of the administration alone will be $1,456,000. Because "each fund shall take care of the insurance of not less than 5,000 persons" (and probably not more) and, since there are 4,000,000 workmen, there would have to be 800 such "funds," each with seven directors, each drawing $5.00 per meeting for the 52 meetings. Multiply it yourself. Now each of these funds (800) must "employ a medical officer" who is "not permitted to practise" and we surely could not expect to pay such a man less than $1,500 per year and this would make another expense of $1,200,000. Each of those funds must do an insurance business for at least 5,000 persons, and this cannot be done on a street curb; those seven directors, at $260 per year, neither would nor could do this work, so they must have offices, and pay rent. Each fund must have a manager and some clerks for the stupendous filing and correspondence, some investigators, some stenographers; telephone service, postage, stationery, and other incidental expenses; surely I shall not be charged with extravagant ideas if I put that figure at $5,000 for each fund or a total of $4,000,000—which, with the other two items would make a grand total of $6,656,000—and not so grand after all, for I have not yet taken into account the tremendous expense of the State administration of those funds through the health insurance bureau for which the bill provides. This commission or bureau must have a commissioner, deputy commissioners, secretaries, an army of clerks, stenographers, investigators, and inspectors; boards of appeal and expensive counsel and all the expenses incidental to a State commission or bureau and this, in the nature of things, must surely exceed the expense of operation of the present Workmen's Compensation Bureau, which was $537,556.32 in 1918, on the basis of cash benefit disbursements of $12,000,000, whereas a compulsory health insurance bureau will dispense $57,945,515 and at the same proportionate cost this will be $2,595,753 or a grand total of $9,251,753, or more than one-seventh of the entire State tax budget for 1919 ($59,000,000), which can only be paid by additional taxation since, as you can see, the average premium has been exhausted by cash benefits to the average employer of $10.56 for his nine days, $2.76 for maternity-equivalent-in-"days-lost" and $1.46 for funeral benefits per average man or a total of $14.48, which leaves only $3.52 for 11.43 days treatment, or 30 cents per day.

Even such a great increase in the State taxes would be a justifiable expense if it could insure health to the workingmen of the State of New York—but is there a Chinaman's chance of any such good results being attained?

The "bad work" of the underpaid and discontented lay workman may be disposed of as a "second" or replaced with much grumbling and at great cost by the deceived and dissatisfied ultimate consumer. Even under such conditions, the home may adapt itself to the inconveniences of poverty and, at the sacrifice of self-respect, accept the charity of the philanthropist or the municipality; even the children can piece out their meager education by attending night classes at the expense of the time which nature demands for recreation and rest; society may hold rebellion, may check it for a time by an amplified police force or an armed State constabulary, or both—but the work which the doctor, the dentist, and the druggist have to do is the conservation, the preservation, and the repair of the public health, and "bad work" here spells disability and death and the consequent withdrawal of tens of thousands from the ranks of workers; an increase in poverty throughout the State; the necessitous occupation of mothers and children; the disruption of the home and the degeneration of society. And this "bad work" is the only kind of work the public may hope for or expect from a profession degraded by law to the status of a contract business. That bill passed the Senate in March, 1919; it did not come before the Assembly for a vote; its reintroduction at the beginning of the next session of the legislature in January, 1920, is definitely promised and one of the paid professional philanthropists who actively lobbied for the Davenport-Donahue compulsory health insurance bill says that the proponents of the bill are campaigning throughout the State to force its passage. They ask the medical profession to subscribe to the principle of compulsory health insurance and submit constructive suggestions. We cannot, in conscience, and will not, in compromise, attempt to amend constructively a measure which is basically vicious; the only honest attitude for us is to say: "Pass it if you dare, we will not help you make it operative. We took the bait when the (federal) Harrison law and the (State) Boylan narcotic law were pending and were lulled into a state of fancied security by some modifications which were made and we relaxed our vigilance; we will not make that mistake again. Once enacted as the law, amendments came thick and fast, and to-day not one doctor, dentist, or druggist in five hundred can say just when (before the court of his conscience or a court of law) he may not be called upon to answer for a crime of omission or commission, try as he may honestly and substantially to comply with the intricacies, and avoid the pitfalls of those laws. Meanwhile, society suffers an alarming increase in the perils of increased drug addiction and doctors who cherish their reputations in the community hesitate to treat addicts.

The doctors, dentists, and druggists have a public duty to refuse to take the initiative or even lend a hand in advancing legislation which they know to be vicious, or which they know will limit their capacity for usefulness to the public, or which they know will limit their earning capacity and the fulfillment of their obligations to their families. They must, in common justice, warn the public of the menace of such legislation and ask its assistance in defeating it. If the public be heedless or indifferent to this warning, the medical professions still have the sacred duty to try to save the public and themselves by refusing to help make the law operative even at the risk of being misunderstood and maligned. I know the thought of organizing a labor union of professional men is horrible to contemplate; I know that if such an organization be forced upon us it will be subject to precisely the same danger of misuse and abuse that occasionally manifests itself in labor unions made up of laymen; with this difference, that public health and life, rather than the public comfort, will be the subject of barter. The patience of the medical profession is exhausted now, and organization for mutual protection is imperative and inevitable. In the future the duty will rest upon the public to encourage the maintenance of the morale of those professions so that the quality of honor among them will reduce the abuse of their power to the minimum.

The medical, dental, and pharmaceutical professions have already organized in Kings, Queens, and many other counties in the State, and have in some instances passed resolutions solemnly declaring that they will not become a part of the machinery for carrying out what they know to be an unjust measure and a rank injustice to them.

In Great Britain, where compulsory health insurance has been in operation, the refusal of the majority of physicians to cooperate, for the same reasons, has caused a failure of the whole health insurance machinery.

I personally wish to emphasize again that I, both as a physician and as an employer, favor the progressive, humane, general principles of compulsory health insurance, but along with the vast majority of physicians of the State of New York I oppose any bill that unnecessarily, arbitrarily, and grossly discriminates against the average physician, dentist, and pharmacist in this State, when it would be good legislation, sound social economics, and simple justice so to amend the Davenport-Donahue bill that is to come up for passage at the present session of the New York Legislature, as to make it satisfactory to the employers and employees, the taxpayers, physicians, dentists, and pharmacists of the State of New York.

ON POSTURE IN DEFECATION.*

By L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

RELATIVELY few physicians or patients appreciate fully the immense importance of perfect intestinal elimination. Constipation is defined in Stedman's Medical Dictionary as "A condition in which the evacuations from the bowels are infrequent or incomplete, more or less fecal matter being retained in the intestine," and in the Standard Dictionary as "A morbid inactivity of the bowels."

Constipation as thus understood is a most common condition among those seeking relief from various maladies, acute and chronic, especially the latter, and yet it is one to which relatively little careful and scientific attention is ordinarily paid; and unfortunately the matter is too often left to the discretion, or indiscretion, of the patient. How often do we hear of well-meaning and otherwise intelligent physicians who inquire only half-heartedly "if the bowels are regular" and then simply direct that they be kept so, "by some mineral water or other means, if necessary," without any specific or explicit directions. The medical profession has itself to blame for the enormous consumption of the extensively advertised laxative and cathartic preparations, mineral waters and mineral oils, from which so many fortunes have been made, to the detriment of the patients and the dishonor of physicians. And yet, when sufficient, intelligent and patient investigations are carefully and repeatedly made, and when proper and positive directions are given, as to both diet and medication, results can be obtained which would surprise those who had not previously given the matter such serious attention.

The subject of constipation and imperfect action of the intestinal tract is a large and most interesting one, upon which volumes have been written. It is not the purpose of the present writing to enter at all fully upon the importance of securing perfect intestinal action, or the means of accomplishing the same, but only to present a single measure which has often proved serviceable as an aid in securing this end.

This relates to the posture maintained during defecation. The modern water closet seat conduces to a tendency of constipation. Being made more and more luxurious it tends to make one sit comfortably, and unless there is considerable expulsive power in the rectum the bowel movement may be incomplete. This is especially true if the call of nature is delayed beyond the usual time of defecation—which should be immediately after breakfast, when the ingestion of food has started peristaltic action, after twelve hours' fasting. By delay beyond the normal time of action there is often a temporary atony of the rectum, which may then extend for an indefinite length of time. With retained feces there or in all the large intestine, there is absorption and consequent autointoxication, with its well-known sequences. The importance of this absorption can be appreciated when we recall how readily various substances are absorbed when given by enemata.

The natural posture in defecation, as assumed by the primitive man, and even to-day by a large portion of the human race, is quite different. Squatting on the ground, with the thighs more or less compressing the abdomen, the position of the pelvis seems to be altered, and in some way the lower bowel more readily empties itself. In many places in Europe privys are furnished only with a raised, horizontal board on which one is expected to squat and answer the call of nature.

In order to overcome the disadvantage of the modern water closet seat very much may be accomplished by having a stool ten or twelve inches high, upon which the feet are placed during defecation. Having myself a tendency to constipation, from sedentary habits and lack of exercise, it has long been my practice to employ this means of relief, and with such benefit that I feel that the method should be more widely known. Time and time again, when by delay or preoccupation of mind there has been rectal atony, and an evacuation was impossible, a good fecal discharge, though perhaps constipated, has been secured shortly by this means. It has also very often happened that when the discharge has seemed small, or inefficient, when seated in the ordinary way, a supplemental evacuation, affording the well-known sensation of perfect relief, has followed the elevation of the feet, in the manner mentioned. This has also often happened when there has been fermentative action with a loose discharge, at first ineffective, but followed by a free and complete emptying of the bowel when the feet were raised.

Mentioning this method of securing a complete evacuation to a young lady patient, among others, she at once remarked to her mother, "Why, that is the way that sister Emily always does." Describing it to a gentleman patient, he said that for a long time he had been accustomed to raising both lids of the closet and squatting on the edge of the china bowl, and that he had also taught his young son to do the same.

In bringing this simple suggestion to your attention I do not, of course, offer it as a panacea or a cure for constipation. As an adjuvant, however, in certain cases it is most practical and valuable. Long experiences in handling cases of chronic disease of various kinds has taught me more and more certainly the immense importance of securing a full and free daily evacuation of the bowels, especially within fifteen minutes after breakfast is finished. With proper care in diet, mastication and mild intestinal stimulants, with the measure suggested this can certainly be accomplished to the very great benefit of the patient. The exact remedies for constipation should always be carefully directed by the physician and never left to the judgment or want of judgment of the relatively ignorant patient, whether rich or poor; and the plan here suggested will often be of material aid in securing the desired result.

This method of aiding defecation may possibly prove to be of value in connection with the medical treatment of cancer, as it is recognized that intestinal intoxication from retained feces is an important element in the production of the latter.

THE IMPORTANCE OF THE SPLEEN IN RESISTANCE TO INFECTION.

WHILE it has been generally accepted for many years that the spleen plays an important rôle in the protection of the individual against infection, there has been very little experimental evidence available in support of this theory and none that could be really called conclusive, either because the number of experiments upon which conclusions were based were too few in number to allow trustworthy inferences, or because possible sources of error were not sufficiently eliminated. Recently, however, these objections have been overcome through the work of Morris and Bullock (*Annals of Surgery*, November, 1919). In the authors' experiments brindle and white rats were used because they could be readily obtained in sufficient quantity, because the operation of splenectomy in them is simple and is rarely followed by complications such as wound infection, hemorrhage, or hernia, and because rats are particularly insusceptible to nearly all the common pathogenic organisms and unlikely to develop infections which would confuse the results. The authors knew the approximate mortality percentage in the rats in their laboratory under normal conditions and they had found the mortality to be due to a septicemia caused by the bacillus of rat plague. They had carefully studied the cultural and other characteristics of this organism and knew the pathological lesions which result from it in rats after accidental infection or intentional inoculation; its cultures can be readily standardized, and as it can easily be recovered from the heart's blood after death, they considered this organism most suitable for their experiments.

In the first series of experiments thirty-six apparently healthy young brindle rats were splenectomized under ether anesthesia. No operative complications, such as hemorrhage or infection, occurred. A similar number of control rats were subjected to laparotomy in which one testicle was removed. As the testicle is larger than the spleen, and the blood vessels entering it are about equal in size to the splenic vessels, its transabdominal removal furnishes a very fair basis of comparison as to the effect of the operative trauma alone upon the subsequent health of the animals. Both sets of animals were found to be active and thriving on the day following operation. They were then exposed to chance laboratory contagion and kept under observation for several months. The splenectomized animals almost invariably died before the controls, and the death rate among them was 80.5 per cent. as compared with 38.9 per cent. in the control rats.

The changes found at autopsy were nearly always in the animals that died spontaneously, whereas in those that were killed as controls they were generally absent. It would seem, therefore, that the authors were correct in their conclusions that the splenectomized rats were more prone to contract the disease and that, having contracted it, they showed less resistance to its ravages. Since the mortality in the splenectomized animals was over twice that in the orchidectomized, it is probable that the lowered resistance of the spleenless animals to chance infection by the bacillus of rat plague was due to the removal of the spleen.

In a second series, 72 brindle or white rats were splenectomized and a like number of control animals orchidectomized. In this series both sets of animals were exposed to chance laboratory contagion and a record of the mortality in each group was kept, none being killed. Three weeks after operation 36 of the splenectomized rats had died of rat plague, against but 7 of the controls; the mortality thus being over five times greater in the splenectomized group than in the controls. At the end of two months 61 rats, or 84.7 per cent., of those splenectomized had died showing the lesions of rat plague infection. During this same time but 21 rats, or 29.2 per cent., in the orchidectomized group had died. This is about the same mortality as that prevailing among stock laboratory rats that have not had operation.

In a third series, 88 rats were splenectomized and a like number orchidectomized, and all were injected subcutaneously with a sublethal dose of a broth culture of the bacillus of rat plague. As the authors say, the effect of this should be to hasten the death of those animals that were susceptible to rat plague, whereas those that had a certain amount of natural immunity would remain in good health and acquire an added resistance. The dose injected produced in the castrated rats 22.7 per cent. of deaths, which is but little or no increase over the normal death rate of nonoperated, uninjected animals. In the splenectomized group, however, the death rate was 87.5 per cent. and the date of death was likewise hastened, so that the majority of these animals died on an average of nine days after splenectomy. All showed the lesions characteristic of rat plague infection.

In still a fourth series, older rats were experimented on to determine whether they too were affected by splenectomy to the same degree, 24 being splenectomized and a like number orchidectomized. All the rats then received a subcutaneous injection of a culture of the rat plague bacillus. Of the 24 splenectomized rats 21, or 87.5 per cent., died within

12 days and positive blood culture was obtained in 90.5 per cent., while but 3, or 12.5 per cent., of the orchidectomized rats died in the two months following operation. The death rate in the splenectomized was thus more than seven times that of the castrated group.

On a comparison of the results obtained in all these experiments the author concludes that, while these animals may get along fairly well without the spleen in the absence of any infection, the reverse is the case when the organism is put to the strain of resisting acute bacterial invasion. Thus it would appear that the spleen normally aids greatly in resisting infectious processes. And if the physiological processes in man are similar to those in rats it is not improbable that the human body deprived of its spleen shows a similar increased susceptibility to infection.

THE DIAGNOSTIC VALUE OF VOLTAIC VERTIGO AND GALVANIC NYSTAGMUS IN DISEASES OF THE MIDDLE EAR AND LABYRINTH.

When a galvanic current is passed through the auditory apparatus of a subject with an absolutely normal state of both ears, or offering only superficial lesions of the auditory canal or tube, the head will always incline towards the positive pole. In acute or chronic suppurative processes of the cavity of the tympanum the inclination is towards the positive pole, but a much weaker current is required than in the normal state. In suppurative processes accompanied by mastoiditis, in chronic and apparently non-suppurating lesions, limited to the transmitting apparatus, and also in subjects who have undergone évidement, the strength of the current must sometimes be very high in order to obtain an inclination of the head toward the positive pole. In mixed lesions of transmission and reception of sound the head will always incline towards the positive pole. In chronic otitis media with a lesion of the anterior labyrinth only a weak current is required to obtain this inclination, while a strong current must be applied to produce this inclination in mixed sclerosis of the middle ear and acoustic labyrinth and in the specific otitides limited to the anterior labyrinth.

In lesions of the vestibular labyrinth, voltaic vertigo undergoes profound changes. In cases of hyperexcitation of the labyrinth, whether acute or chronic labyrinthitis, in hemorrhage or sclerosis of the labyrinth or its partial destruction on one side only, the inclination of the head will be towards the diseased ear, whether the negative or positive pole is applied on the mastoid. When the lesions are bilateral the inclination will be towards the ear the most seriously involved. In affections of the posterior labyrinth comprising a double lesion which causes an equilibrium, or a bilateral destruction of the labyrinth, there is neither inclination of the head nor of the body. In lesions of the middle ear and acoustic labyrinth, the decrease or increase of the electric resistance alone is important. In lesions of the vestibular labyrinth, inclination toward the affected ear in some cases, and no inclination whatsoever in others, are two most important phenomena.

The sensation of vertigo during the passage or interruption of the current appears to be of little diagnostic value, but it may be said that it is almost always present in lesions of the posterior labyrinth. In only one of the many patients examined by Bouteil, did it accompany the retropulsion which took the place of lateral inclination. As to galvanic nystagmus, the reaction when the current is opened is equal to that occurring when the current is interrupted in a normal subject, whether the cathode or anode be placed in front of the tragus of the ear submitted to the test. In auricular lesions with participation of the labyrinth, Bouteil found the following reaction formula:

$$\begin{aligned} &CaCR < CaOR \\ &AnCR > AnOR \end{aligned}$$

In lesions limited to the middle ear, he found the following modification of the formula:

$$\begin{aligned} &CaCR < CaOR \\ &AnCR > CaOR \end{aligned}$$

The strength of the current necessary for producing galvanic nystagmus is of considerable diagnostic value; the more excited the posterior labyrinth, the weaker the current necessary for the production of the phenomenon. A very strong current is required when there is partial or complete destruction of the posterior labyrinth.

HEMATOMA OF THE OPTIC NERVE SHEATH.

From the etiological viewpoint, hematoma of the optic nerve sheath may succeed either a cranial traumatism accompanied by subdural hemorrhage or a spontaneous meningeal hemorrhage. Finally, some writers have described a primary spontaneous hematoma occurring without any intracranial hemorrhage. Cranial traumata are the most frequent etiological factors of the process under consideration, more than 50 per cent. of the cases being due to this cause. The nature of the traumatism is of little importance. Be it a fracture of the base or the vertex, a gunshot wound, a contusion or wound of the brain, the only condition necessary for its production is that the traumatism be accompanied by a sufficiently severe meningeal hemorrhage for the blood to infiltrate into the optic nerve sheath. The origin of the hemorrhage is usually one of the vessels of either the pia mater or the brain, but it may also come from the middle meningeal by a rather special mechanism, namely, that rupture of the artery is accompanied by a laceration of the dura permitting the formation of two hematomata communicating with each other, one being situated under, the other above the dura. If the dura is not lacerated the blood can only strip it up, thus realizing the classical picture of hematoma of the middle meningeal, but it cannot penetrate into the optic nerve sheath.

Some are of the opinion that fracture of the optic canal is a necessary condition for the formation of a vaginal hematoma and von Hoelder, out of a total of fifty-four cases, found a fracture of the optic foramen in forty-two, but his statistics have only a relative value because the autopsies were made for the most part in cases of gunshot wounds, the shot having been fired into the mouth. Mardellis and Cantonnet likewise maintain, with some reservations, that fracture of the optic foramen is essential for the production of hematoma of the optic nerve sheath, but fracture may occur without necessarily producing a hematoma and vice versa. Berlin and Uhtoff, on the contrary, think that fracture of the optic canal is far from giving rise to this lesion, and they point out that cases are not wanting in which the canal was intact. Finally, the hematoma being most usually bilateral, it is difficult to conceive that in all the cases there should be fracture of both optic canals. It is therefore probable that the true source of blood in the optic sheath is a subdural hemorrhage, that fracture of the optic canal is uncommon in connection with this lesion, and that in instances of hematoma purely of the sheath it has no etiological value.

In spontaneous meningeal hemorrhage is to be found all the causes for hematoma of the optic sheath. In the first place cerebral hemorrhage should be mentioned, accompanied by a subarachnoid collection, while another equally important etiological factor is hemorrhagic pachymeningitis. Sometimes the hematoma is produced by rupture of an aneurysm, and lastly, all affections accompanied by circulatory disturbances capable of causing hemorrhage, such as diabetes, interstitial nephritis, or scurvy, may give rise to it. But it is to be noted that in the latter cases the hematoma of the optic sheath is only an epiphenomenon and it is difficult to detect its peculiar physiognomy in the midst of varied disturbances which are at the same time produced by the casual disease.

The question of spontaneous, or rather primary, hematoma of the optic sheath, due to a local primary lesion of this sheath, is most interesting. It is unquestionably rare, and Gouin never came across an instance in several hundred eyes he examined after enucleation for the most varied lesions. There is, however, one unquestionably authentic case of primary hematoma of the optic sheath. This is a specimen in the collection of the ophthalmological clinic of the University of Lyons. The hematoma in this case was due to an obliterating arteritis.

A POSSIBLE CAUSE OF PSORIASIS.

A NEW and ingenious theory of psoriasis is advanced by Dr. George Elliott of Toronto in a paper in the *Medical Press* of November 26, 1919, in which he compared human skin to vulcanized India rubber. Sulphur, he says, plays a predominating part in the vulcanization of rubber, rendering it more elastic, durable, malleable, resisting, and impermeable. Eliott explains minutely why, according to his belief, man has a vulcanized skin. The three striking features of the sectional histopathological picture thus described are: The disintegrated white blood corpuscle collections among the cells of the corneum, or as they have been called, the cold or chronic abscesses of that layer; the increase in the number of prickle cells, especially in the interpapillary spaces, and their absence over the apices of the cones, and the absence of any parenchymatous edema of the prickle cells. In pursuit of the analogy Elliott recalls the fact that when too much sulphur goes into the vulcanization of rubber this becomes brittle. Now, the white blood corpuscles, he says, have carried too much sulphur to the prickles of the rete, so that they become brittle and fail to keratinize; this process in the human skin being comparable to the vulcanization of rubber. The increase in cellular production of the interpapillary body is an effort on the part of nature to take up and assimilate the surplus sulphur—a "speeding up," as it were. In short, in psoriasis there is an overcharging of the cutaneous system with sulphur, a diminished excretion of sulphates, and an aberration in the requisite sulphur content which fails to produce the exact vulcanization of the normal skin. Elliott points out that clinically the theory of variability in vulcanization appears to be confirmed. For instance, there is a deficiency of keratin in the scales of psoriasis, and the nuclei persist in these, this condition of parakeratoris being thereby distinguished from hyperkeratoris in which the nuclei are absent.

Climate has a distinct influence on the incidence of psoriasis, but this is obviously due, Elliott thinks, to the fact that in the cold or even in temperate climates large amounts of nitrogenous foods, which abound in sulphur, are consumed. Therefore, it would seem that psoriasis is a dietetic disease, because it is largely due to the consumption of more sulphur than certain individuals are able to use or eliminate, although cold in itself appears also to predispose to this form of skin affection to some extent. Free perspiration, which takes place in tropical climates, will tend to eliminate sulphur, irrespective of diet, and possibly this is one reason why psoriasis seldom or never occurs in the tropics. Elliott's theory is ingenious and invites to further study of this intractable disease of the skin.

THE "FIXED PERIOD" FOR ATTENDINGS.

PLANS for limiting the period of service of attending physicians and surgeons in the hospitals are common in Europe, rare in this country. When a distinguished man has served a hospital for a great many years, and continues to make rounds and direct the service when his professional flame needs oil, it is a very delicate and embarrassing matter for a board of governors to request his resignation. Such a situation is usually averted by the doctor's recognition that his work is deteriorating, and by his subsequent voluntary resignation. But unfortunately attendings are still occasionally seen who in

the earlier years of their service may have done valuable work—work stimulating to the younger men under them, but who later have failed to impart to their students and subordinates a single new idea, who have grown "set in their ways," and hence scientifically of less value. Certainly, limiting the service of an attending physician to, say, ten years, would be of great benefit to hospitals, to patients, and to progress in the profession. It would encourage the younger men. It would keep the service from growing stale. It would infuse new ideas into what is now often impenetrable hospital routine.

Undoubtedly there are great doctors who are always keenly alive, always stimulating. Any hospital would be loath to part with the services of such men at the expiration of ten years. But hospitals should bend their efforts toward recognizing rising medical generations, and toward more accurate appraisal of their professional worth, in order that there need be less fear of replacing older men by younger, and less tendency to hold on to an older man at all costs. According to Morris, in his "History of the London Hospital," each physician or surgeon after twenty years' service as such, retires, and his place is usually filled by the senior of the assistant physicians or assistant surgeons. Burdett, in his "Hospitals and Asylums of the World," mentions several plans of limiting the service of attendings: one, that they shall be subject to reelection by the Governors each year (which amounts to service during good behavior); another, that the appointment shall be for ten years, subject to reelection (not essentially different), and another, that the attending shall retire at the age of sixty. A few hospitals abroad have adopted a fixed and relatively short term of service, often as short as five years. The plan deserves more consideration on the part of hospital authorities in this country.

The Postoperative Febrile Reaction of the Malarial.

Every surgeon who has operated on malarial subjects, states Dr. Brun of Tunis (*La Presse Médicale*, Dec. 13, 1919, xxvii, 76), has seen temperature rises supervene. If the practitioner is not familiar with this behavior he will naturally be very apprehensive and mystified. During the war surgeons who operated on French colonial soldiers saw this postoperative fever supervene after trifling operations, like simple suture, upon the evening of the operation day. Had they known it a simple hypodermic of quinine could have prevented or could have jugulated this manifestation. At the Hospital Sadiki in Tunis the author has seen a host of such cases, for this rise of temperature is the rule in the chronic malarial subject. The anemia and splenomegaly with the recurrent attacks of fever in subjects resident in a malarial region should leave no doubt as to the nature of this rise even in the absence of blood tests. The choice of anesthetic plays no rôle here. The temperature attained is nearly or quite 104° F. Paradoxical and puzzling in these fever accesses is absence of preliminary chill. The pulse does not show a parallel rise and 100 appears to be the limit, while it may not exceed 80. All in all the temperature rise is hyperthermia rather than true fever. Doubtless the phenomenon is well known to our own surgeons who live in malaria-ridden countries, but we do not at this moment recall any recent literature on the subject and if it occurs it is doubtless accepted as a matter of course with prophylactic quinine before or after intervention.

Diagnostic Significance of Phthiriasis.

A brief article on this subject, written by Jeanselme and published in *La Médecine* for November, 1919, i, 2, recalls the primrose of the poet which, whatever it might mean to the imaginative, could mean nothing but a primrose to the pragmatic. Between two men afflicted with pediculosis there would ordinarily be little to differentiate, at least until they had been deloused. The author, however, shows that the existence of this parasitism *per se* and in its various degrees may have much significance, because simple lack of hygiene and of change of underwear do not constitute the entire problem. Of two men equally exposed one may become very lousy and the other escape to a certain extent. The very indolence and indifference which makes one insensitive to his condition may be due to some deep-seated ailment. The insensitive skin of the leper makes him indifferent to the ravages of the itch mite, and as a result the neglected leper of Norway formerly developed a degree of scabies hardly conceivable in the days of segregation. The same factors obtain in pediculosis. The subject who suffers in a marked degree may be found to be demented or insane. He is very apt to be cachectic, and the chances are that under these circumstances he will be found suffering from occult cancer, tubercle, diabetes, or some other constitutional affection. In other cases the basis condition is senescence or senility. Jeanselme lays down a maxim based on a wide experience—whenever a subject is encountered with "florid" phthiriasis he should be submitted to a thorough internal examination.

News of the Week.

British Birth Rate Shows Gain.—The official returns show that more babies were born in England during August than in any previous month since the beginning of the war, there being 6,390 births, equivalent to an annual birth rate of 18 per thousand. That means 461 more babies than for the same month of 1918. The report shows a preponderance of boy babies which seems to be in accordance with the belief that more boys are born during periods of stress, hardship, and food shortage, and more girls during periods of wealth, ease, and luxury.

Record of Army Nurses Overseas.—The final report on the army nursing service abroad shows that between May 8, 1917, and May 31, 1919, 10,245 nurses out of a total of 21,480 enlisted for war service overseas. Of these three were wounded and 266 died while on duty. The report declares

that the work done by these women from July 18 to November 11, 1918, was such that no praise would be great enough. The nurses worked from fourteen to eighteen hours a day for weeks at a time. On armistice day there were 181,421 American soldiers, sick and wounded, in hospitals and there was a shortage of 6,925 nurses. It is said that nurses dropped from fatigue around the operating tables, but complaints were almost never heard.

Red Cross Gives Accounting.—The War Council of the American Red Cross has issued the first installment of the complete report of the activities of the Red Cross during the war. Out of a total expenditure of $273,000,000, a sum approximating $119,000,000 was spent in the United States. For every dollar of the $400,000,000 in money and material collected, more than a dollar and one cent was available for war relief, due to the interest earnings on the funds reaching a total of over $2,766,000. The following figures give some conception of the undertaking directed by the war council. There were engaged in Red Cross activities 8,100,000 persons; 371,577,000 articles were produced by volunteer workers; the families of soldiers aided numbered 500,000; knitted articles given to soldiers and sailors numbered 10,000,000; there were shipped overseas 101,000 tons of supplies. The Red Cross worked in twenty-five different countries. In France 1,155,000 patient days were given in Red Cross hospitals. The French hospitals given material aid numbered 3,780. There were 294,000 splints supplied to American soldiers. The men served by Red Cross canteens numbered 15,376,000. There were 1,726,000 refugees aided in France. On May 1, 1917, just before the appointment of the War Council, there were 562 chapters with a membership of 496,194 adults. On February 28, 1919, there were 3,724 chapters, embracing a membership of 20,000,000 adults and 11,000,000 juniors.

New York Starts Health Campaign.—At meeting of the Executive Committee of the Greater New York Red Cross Christmas Seal Campaign, on October 17, plans were outlined for a health education campaign to embrace every part of the Greater City and to form the basis of a better system for the prevention and cure of tuberculosis. Attention was directed to the fact that while 67,882 American soldiers, sailors, marines and others were killed during the year in which the United States was engaged in the world war, 150,000 men, women, and children at home died from tuberculosis. New York's deaths from tuberculosis number a little more than 10,000 a year, but Board of Health statisticians declare that only one sufferer from tuberculosis in twenty-five is registered. Dr. Haven Emerson presided at the meeting. Among others interested in the campaign are Health Commissioner Dr. Royal S. Copeland, Dr. Herman M. Biggs, Dr. James Alexander Miller, Dr. Thomas J. Reilly, Dr. Walter G. Frey, and Dr. John S. Billings, Jr.

Roosevelt Memorial Tablet for Hospital.—A Roosevelt memorial tablet, the gift of Mrs. Whitelaw Reid, was recently placed in the Orthopedic Hospital, New York City. The tablet was presented in recognition of Colonel Roosevelt's services to the institution which was founded by his father.

Memorial Hospitals Assured.—The Campaign Committee for the Memorial Hospitals Fund, having for its purpose the construction of new buildings for the Jamaica Hospital and St. Mary's Hospital in the Borough of Queens, reports that the total amount subscribed was $148,840, of which about $66,500 has been paid in and the balance is to be paid in installments.

The Goodhue Home for Convalescent Children.—The Federated Neighborhood Association has issued a report reviewing the work done at Goodhue, its summer home for undernourished children, at New Brighton, Staten Island, N. Y. During the summer 697 children were cared for, the average stay for each child being 15 days. Every child was given a thorough physical examination before going to the home and on his or her return. The records of 520 children have been analyzed thus far and show an average gain of 2 1/3 pounds for each child, during a stay of 14 days. The greatest individual gain was nine pounds by two different children, while four gained eight pounds each. Twelve of the children lost in weight a little over one pound each, and 48 failed to show any change in weight during their stay. An analysis of the ailments of those children who did not gain showed that enlarged tonsils and defective teeth predominated. With the present prices of food it is estimated that it cost about $5 per pound to increase a child's weight.

Idaho Doctors Warned of Prosecution Under New Registration Law.—The Idaho Legislature, at its last session, passed Senate Bill No. 187 requiring all professions licensed by the State Department of Law Enforcement to pay an annual renewal fee of $2, on on before July 1 of each year. About 100 doctors have failed to register and pay this fee, and it is believed that possibly many doctors in the State have not received notice of this change in the law. The Secretary of State and Commissioner of Law Enforcement have issued a warning that physicians failing to comply with the law will be cited to appear before a medical tribunal to show cause why their license should not be revoked, and those who do not pay the fee after such opportunity will be prosecuted by the department as practising medicine without a license.

Scholarship in Surgery for French Women.—The National American Woman Suffrage Association announces that the remainder of a sum of nearly $200,000 raised by suffrage States for the maintenance of the Women's Oversea Hospital, will be used to found a scholarship for the training of French women physicians, part of the training to be taken in the United States.

The United States Training Corps for Women.—The *Public Health Reports* publishes the program of the United States Training Corps for Women, which was organized by Miss Susanna Cocroft as the outcome of her training courses for women working in the Government departments. In 1918 Miss Cocroft went to Washington and offered her services, believing that a course of physical training somewhat similar to that given in the military camps would benefit the average woman. Her offer was accepted and over 3,500 women availed

themselves of the opportunity to learn under expert guidance, in the early morning and late afternoon hours, breathing and setting-up exercises and the quick reflex mental alertness necessary to the accomplishment of military maneuvers. The plan formulated by Miss Cocroft calls for the establishment under the auspices of the National Government of a large number of training camps for women in different parts of the United States, the camps to be permanent or temporary according to the local controllable conditions and indications. A practical test of the plan was made at "Camp Geneva," established and operated on the shore of Lake Geneva, Wis., in August, 1919.

Charitable Bequests.—By the will of the late Henry C. Frick the following institutions are to receive shares of the "rest, residue and remainder of property and estate of whatsoever nature and wheresoever situated," other bequests having been taken care of: The Children's Hospital, the Allegheny General Hospital, Mercy Hospital, the Free Dispensary, the Western Pennsylvania Hospital, all of the City of Pittsburgh; the Uniontown Hospital in Fayette County; the Cottage State Hospital, in Connelsville, Fayette County; the Westmoreland Hospital, in Greensburg, Westmoreland County; the Mount Pleasant Memorial Hospital of Mount Pleasant, Westmoreland County; the Bradock General Hospital of Allegheny County, the Homestead Hospital of Homestead, all of Pennsylvania; and the Society of the Lying-in Hospital of the City of New York.

The Yale School of Medicine receives for general endowment property valued at $200,000 by the death of Mrs. Levi Shoemaker, of Wilkes-Barre, Pa. Mrs. Shoemaker was the widow of the late Dr. Shoemaker.

Mr. H. A. Metz has donated the necessary funds to the Volunteer Hospital, of New York, for the installation and development of a urological and syphilological department, in both the hospital and its dispensary. It is the hope of the donor that the department will not only be able to do the usual work of such a subdivision but that it will also engage in research work.

Dr. Charles A. Rosewater has resumed his practice at 40 Milford Avenue, Newark, N. J.

Dr. L. Duncan Bulkley and **Dr. L. Buckley Cady** have removed their offices from 531 Madison Avenue to 39 West Fifty-eighth Street, New York City.

Medical Society Elections.—The KENT COUNTY MEDICAL SOCIETY, at its annual sessions held in Providence, R. I., December 5, elected the following officers for the ensuing year: *President* and *Treasurer*, Dr. Frank Bailey Smith; *Vice-President*, Dr. Benjamin F. Tefft; *Secretary*, Dr. J. Fulgence Archamboult; *Censor* (for two years), Dr. H. Barton Bryer; *Censor* (for three years), Dr. Fenwick G. Taggert; *Delegate to State Medical Society*, Dr. Charles S. Christie.

THE RANGER MEDICAL SOCIETY, of Ranger, Texas, which was organized November 4, elected the following officers: *President*, Dr. C. O. Terrell; *Vice-President*, Dr. H. K. Weir; *Secretary*, Dr. Carl Wilson; *Treasurer*, Dr. Rutherford.

THE SOUTHERN HOMEOPATHIC ASSOCIATION, at the closing session, November 21, of the annual convention held in Cincinnati, elected the following officers: *President*, Dr. A. L. Smethers, Anderson, S. C.; *First Vice-President*, Dr. M. L. McCreary, Knoxville, Tenn.; *Second Vice-President*, Dr. G. W. Johnson, Danville, Va.; *Corresponding Secretary*, Dr. H. B. Bader, Richmond, Va.

THE CONNECTICUT PUBLIC HEALTH ASSOCIATION, at its annual meeting held at Hartford, November 21, elected the following officers: *President*, Dr. C. J. Bartlett, New Haven; *Vice-President*, Dr. Elias Pratt, Torrington. The remaining officers were reelected.

THE THIRD (GEORGIA) DISTRICT MEDICAL ASSOCIATION, at its recent meeting held at Cordele, Ga., elected Dr. Lucius Lamar, of Dawson, as *president* for the coming year, and Dr. Greer, of Oglethorpe, was reelected *secretary*. The next annual meeting will be held at Montezuma.

THE SOMERVILLE (MASS.) MEDICAL SOCIETY, at its annual meeting, December 4, elected the following officers for the ensuing year: *President*, Dr. M. M. White; *Vice-President*, Dr. George C. Mahoney; *Secretary-Treasurer*, Dr. Edmund H. Robbins.

The MEDICAL ASSOCIATION OF ANDROSCOGGIN COUNTY (Maine), at its meeting on December 2, elected the following officers: *President*, Dr. Leo Hall; *Vice-President*, Dr. William Ness; *Secretary and Treasurer*, Dr. S. L. Andrew; *Delegate*, Dr. A. W. Plummer.

The BRIDGEPORT MEDICAL ASSOCIATION, at its annual meeting on December 2, elected the following officers for the coming year: *President*, Dr. Dorland Smith; *Vice-President*, Dr. Charles W. Gardner; *Secretary*, Dr. C. Virgil Calvin; *Treasurer*, Dr. Robert H. Strang; *Librarian*, Dr. George B. Garlick.

The PORTLAND (Maine) MEDICAL CLUB at its annual meeting on December 4 elected the following officers for the ensuing year: *President*, Dr. E. Gehring; *Vice-President*, Dr. E. W. Files; *Secretary and Treasurer*, Dr. D. Forrest Weeks; *Board of Censors*, Drs. B. F. Dunn, C. O. Haskell and S. B. Seavey.

The JEFFERSON COUNTY MEDICAL SOCIETY, at its annual meeting in Birmingham, Ala., December 3, elected the following officers for the coming year: *President*, Dr. E. M. Mason; *Vice-President*, Dr. R. E. Cloud; *Secretary and Treasurer*, Dr. G. W. Rogers.

Obituary Notes.—Dr. J. ELLIS RODLEY of Chico, Butte County, Calif., died December 3. Dr. Rodley, who was born in Galashields, Scotland, in 1852, was graduated from the Missouri Medical College, St. Louis, in 1881. He had practised in Chicago since 1888.

Dr. WALTER L. HAVENS, of Chester, Vt., died December 7, after a long illness, at the age of 68. Dr. Havens was graduated from the College of Physicians and Surgeons, Columbia University, New York City, in 1885.

Dr. FLORENCE NIGHTINGALE WARD, one of the first American women to study medicine in European hospitals, died December 16, at the age of 59. She was graduated from the Hahnemann Medical College of the Pacific, San Francisco, in 1887. Dr. Ward, who before her marriage to Dr. James William Ward, was Miss Ferguson, was a native of San Francisco.

Correspondence.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, December 5, 1919.

Epsom College, the British School With a Medical Foundation.—In all countries, it occurs frequently that medical practitioners when they die leave little or no money, or when they reach an age when practice is impossible, or when they are incapacitated by an organic disease such as heart disease, are in a necessitous condition. In case of death, the lot of their wives and families is often pitiable and in case of incapacitation by age, by illness, or by accident the fate of themselves and dependents is often no less deplorable. Something has been done in England to assist persons in this condition. Some sixty-six years ago one John Propert, a medical man, founded the institution now known as Epsom College. It has a twofold object. First to provide pensions for medical men and their widows in reduced circumstances and secondly, to give an education of the highest class for their sons. Pensions of £30 a year are given to fifty aged and impecunious medical men or their widows while fifty sons of necessitous or deceased medical men are not only afforded a first-class education, but also receive gratuitous maintenance, clothing, and pocket money. The sons of medical men, irrespective of the Foundation boys, are received on lower terms than the sons of the nonmedical members of the community. Consequently the College always contains a nucleus of the sons of medical men, and to a large extent, is a recruiting ground for the medical profession. The endowment of the College has never been nearly sufficient for its maintenance upon the lines sketched above, and its continuance in its present form depends upon the generosity of the medical profession and the general public. The annual sum of £4,500 has to be raised by subscriptions in order to carry on adequately this good work. The response throughout the war despite the nervous strain and financial stress has been such that no lapse of the work has occurred but the pinch has been and is being felt and Sir Henry Morris, the honorary treasurer of the College and Foundation, has issued an earnest appeal for help. It seems that there should be in every country not one but several institutions resembling Epsom College, adapted, however, to the special needs of the country in which they are situated. The member of no profession earns, on the whole, so precarious a livelihood as he of the medical profession. The big or even moderately big fortunes left by medical men can be counted on the fingers of one hand while those who die absolutely poor or leaving but a paucity of the world's goods for the support of those they leave behind are numerous. Epsom College has fully justified its establishment and may fitly serve as a model in some of its features for the foundation of similar institutions in other countries.

Annual Report of the Chief Inspector of Factories and Workshops for 1918.—This is the first report of this kind issued since the end of the war although it deals mainly with the last year of the war. It differs in several important respects from reports from the same source of previous years. It is not a matter of fact technical account of the subjects with which it deals, but rather a highly interesting and instructive narrative of the progress of industrial hygiene. The reason for the altered tone is not far to seek. It is indicative of the changed attitude of employers and officials toward the employees. The employed now is not regarded as more or less a part of the machinery of a factory or workshop, but as a human being. The war was largely responsible for this new point of view. It was found that if the employed were not overworked, that is worked to the verge of fatigue, were well fed on appropriate food, were looked after hygienically, made comfortable and provided with amusement to relieve the monotony of toil, the output was better by far in quality and quantity.

It has been recognized only recently that a fruitful cause of industrial trouble is the infinite boredom of minding machinery. Labor-saving devices, and the high organization of labor increase production, but, at the same time lessen the workman's pride and pleasure in his work. In manual labor when the result is dependent on the workman's skill and perhaps imagination, zest and interest are aroused and boredom banished. The ceaseless supervision of the doing of a purely mechanical action does produce a nervous strain and a loathing of monotonous labor that manifests itself in various ways but in a social rather than in a physical manner, generally in going on strike. Lord Robert Cecil, who by the way, is very much of a democrat, thinks that the best mode of helping the worker to get over this strain without imperiling production, is to take pains to make him aware of the significance of the business in which he is engaged, to tell him where his product is going, how it is sold, who uses it, and to make him understand, if possible, where his share in the manufacture comes in.

The officials of the British Home Office responsible for the medical inspection of factories and workshops and for the issue of the report, have shown themselves more cognizant recently of the importance of industrial hygiene and of that part of it which intimately concerns the welfare of the workers. The facilities provided for personal hygiene have been vastly improved in British factories and workshops of late years, and the object appears to be now, to make the workpeople contented not only by rendering the factories clean, well ventilated and sanitary, but also and especially by making them as comfortable as possible. Cleanliness, comfort, and amusement appear to be the slogans in demand and use in dealing with the employed in factories and workshops in the country.

Accident prevention and safety first methods in vogue in many British factories have a familiar sound to one who has lived in America. According to the report the methods have been effective, but it is stated that there is room for an even wider campaign. Recognizing that there is need for much educational work, the Home Office is cooperating in the efforts of the British Industrial "Safety First" Association to deal with the institution of safety first measures in factories and workshops.

Showing which way the wind is blowing with regard to the supervision of women workers in factories, Miss A. M. Anderson, writing in the report, states that a conference, convened by the British Association for Industrial Reconstruction, between organizers of trade unions, Bristol employers and others concerned with the industrial employment of women, was held at Shipham, Somerset, during the year 1918. The conference, including trade union leaders and employers, gave decisive support to the movement for a new humanizing of factory conditions by methodical administrative means. After animated debate, not free from warm arguments, even "supervision" of welfare of the right kind was admitted as indispensable. As to the vote of the Ministry of Health in promoting industrial hygiene, nothing is known of yet. The housing question is the most pressing one of the day, and Dr. Addison and his coadjutors will have their hands full for some time in trying to solve this problem, the successful solution of which is so essential to the health of the people at large.

Preventive Treatment of Influenza.—Sir Thomas Horder lectured recently on the preventive treatment of influenza before the Southern Branch of the British Medical Association. He said in part that medical men were so much in the dark concerning the factors which determine epidemics of disease, and especially of influenza, that this branch of medicine was almost barren of results. For the individual to keep fit was sound advice, but it did not touch the root of the matter. Influenza attacked the weak and strong as the rain fell on the evil and the good. Whether the causative agent was Pfeiffer's bacillus, or some other microbe as yet not isolated, possibly a member of the "ultra-microscopic" group, could not be said. Sir Thomas went on to describe a number of experiments with Pfeiffer's bacillus, in which the bacilli had been sprayed in enormous quantities into the nose, eyes and throats of volunteers without producing any results, and virus taken from influenza patients sprayed in similar fashion, also failed. More work was required on the etiology of influenza. The onus lay, not on the practitioner, but on the government. Money spent on national health was the soundest investment the nation could make. The speaker concluded by saying that he was generally in favor of prophylactic vaccine because it conferred a certain degree of protection. But preventive inoculation of single individuals taught little. He urged that large stocks of vaccine should be placed at the disposal of medical officers of health, who should cooperate with medical officers in charge of institutions and be responsible for collating the results.

4. Benzyl Benzoate.—J. Morton Boice, in a résumé of the work done by various observers on this nonnarcotic antispasmodic, offered as a succedaneum for opium, papaverin, etc., discusses the history, chemistry, pharmacology, therapy, clinical results, and dose and administration of benzyl benzoate, an ester of benzyl alcohol and benzoic acid. From this study he holds that while the results thus far attained do not seem to be more than relatively conclusive, the apparent nontoxicity of the drug seems to warrant a more extended and thorough trial at the hands of the profession. Where an antispasmodic of the opium type is indicated, for its relaxing action on the unstriped muscle fiber, it would seem to be fair to try out benzyl benzoate in conditions such as dysmenorrhea, asthma, diarrhea, arteriosclerosis, and esophageal and pyloric strictures.

2. The Gastric Hypermotility Associated with Diseases of the Gallbladder, Duodenum, and Appendix.—Stewart and Barber state that there are two means of studying the reflex activity of the stomach: the review of recent hospital records, and the duplication, as far as possible, of the human disease equations in the experimental laboratory. The reports of gallbladder, duodenum, and appendix cases in the Third Division, Bellevue Hospital, from 1911 to the present time, have been reviewed, and from these have been selected only those cases with full roentgenographic reports based on complete gastrointestinal examination confirmed or modified by direct inspection of the open abdomen. In those few instances in which the roentgenographic diagnosis did not correspond to the actual findings at operation, the error, which was one of inference and not of observation, was corrected. The pathological findings have been purposely omitted; their significance, as far as the stomach function is concerned, may be the measure of the stimulation or depression of the stomach. From these surveys, which are tabulated and illustrated, the following summary is drawn: 1. For the past eight years the records of chronic cholecystitis, with or without cholelithiasis, duodenal ulcer, and chronic appendicitis bearing roentgen-ray notes on the gastric motor function and verified by open operation, disclose gastric hypermotility for gallbladder disease in 68.4 per cent., for duodenal ulcer in 75 per cent., and for chronic appendicitis in 55 per cent. of cases. 2. Experiments purposely carried out in the open surgical abdomen antedating this clinical review give hypermotility for gallbladder disease in 61.5 per cent., for duodenal trauma in 66.7 per cent., and for appendix disease in 100 per cent. of experiments. 3. The motor characteristics of surgical lesions of the stomach are the incisura, pylorospasm (pyloric-sphincter-spasm) in that they probably more frequently occur in the presence of essential disease. Diffuse pylorospasm appears very often "reflexly."

1. Voluntary Muscular Movements in Cases of Nerve Injuries.—Frederic Wood Jones holds that the story of the European war will almost certainly reveal to future generations that the scientific neurologist gained more real insight into the physiological basis of sensation than did the orthopedic surgeon into the principles of muscular movement. The scientific neurologis, by reason of his special training, was accustomed to think in terms of the central nervous system, whereas the surgeon naturally thought in terms of the peripheral motor nerves. The orthopedic surgeon, and his many trained assistants in special departments, may possibly have somewhat overlooked the importance of the cerebral cortex in the technical refinements of operative procedures on peripheral nerves; whereas the scientific neurologist looked first to the cortex in his dealings with those derangements of sensation, dependent upon wounds, which were relegated to his care as a physician. As far as the socalled sensory area of the cortex is concerned, the quality of sensation lodged within the gray matter of the post-central gyrus consists in a discriminative appreciation of the spatial relations of a part. As a corollary of this, it may be laid down as a truth that within the socalled motor area of the precentral gyrus is lodged the voluntary power to initiate an alteration in the position of a part, the spatial relations of which are appreciated in the post-Rolandic area. This power of altering the spatial relations of parts is conferred by the agency of the contractile muscles, and since these muscles react in response to a volition for spatial alteration, we are accustomed to misname them as voluntary muscles. Muscles are the ministers of movement, and some of them take part in voluntary movements, since the spatial relations of the parts upon which they act are appreciated by the cortex; but only to that extent may any muscle properly be termed "voluntary." Most muscles act in four separate capacities. When a muscle group directly affects the movement of volition, it acts as a *prime mover*. When a muscle group acts in direct (but in coordinated and harmonious) opposition to the movement of volition, it acts as an *antagonist*. When a group of muscles prevents some undesired but possible action of the prime mover, it acts as a *synergic*. When a muscle group acts in order to steady a part from which a prime mover acts, it acts as a *fixation* muscle. In the whole range of muscular activities there is only one rôle (that of prime mover) which at all fulfils the conception of a voluntary muscle performing the task set by the will. Many who have performed the operation of tendon transplantation have imagined that an elaborate preparation by reeducation would be necessary before the muscles could take up their new rôle as prime movers. It has commonly been supposed that a flexor muscle would need some special training before it could play the altogether different part of an extensor. If the technique of the operation falls short of perfection some difficulty is experienced by the patient in bringing the transplanted muscles into play, but some simple mechanical reason for this is usually apparent. If the technique of the operation leaves the transplanted muscles in a mechanical position for discharging their new function at once, this function will be readily exercised. The flexor muscles have become the mechanical ministers of the movement of extension, and the cortex desiring the realized spatial alteration connoted by extension will use whatever agents are at hand. The only physiological problem which has to be solved in the central nervous system is the dissociation of the transplanted muscles from the action of the undisturbed members of their group. This apparent difficulty is one which as a rule is readily overcome, and the transplanted flexors act as prime-moving extensors without exciting any antagonistic action in the untransplanted flexors. It may indeed be questioned if the after treatment of cases of tendon transplantation is best carried out by those sufficiently instructed to appreciate the apparent great disturbance that has taken place in neuromuscular physiology. It is, at any rate, certain that if both patient and attendant are innocent of any desire to probe into abstruse details of the laws of movement extremely good restoration of function may be obtained. While a muscle the tendon of which is transplanted may readily perform its new function as a prime mover, it is very different with other activities in which it normally takes part. As an illustration of this, in a case of perfectly successful tendon transplantation, a wrist flexor turned into a wrist extensor does not act in this way. When the patient can extend the wrist and the digits in a perfectly ordered and powerful manner, his transplanted muscles still fail him as synergics. Under these circumstances flexion of the digits is accompanied by flexion of the wrist, and the greater the effort to grasp the more completely flexed does the wrist become. The readiness with which transplanted muscles are used to carry out movements not normally performed by them affords an excellent example of the utter disregard which cortical volition displays for its agents. Faulty estimates of the exact damage done to nerves by war injuries were nearly always the outcome of the clinician expecting graver and more widespread loss, both of sensation and of movement, than is met with in actual practice. Present methods of anatomical teaching are held responsible for this and other errors of judgment in the diagnosis and prognosis of nerve injuries. Failure to realize the cortical power for utilizing any agent of movement is apt to lead to disaster in muscle reeducation, of which so much has been heard of late. This art comprises all grades of treatment, from the terrible monotony of repetitive mechanical movements (which the writer likens to a form of punishment formerly reserved for criminals) to the intelligent cooperation of attendant and patient in the performance of voluntary and purposive efforts. Much good has resulted from this last type of reeducation, but it must be remembered that the more the cortex of the patient is employed in the task, the more must one be on guard against stimulating him to employ muscles which are not paralyzed to perform the task normal to muscles which are, or have been, thrown out of action, but which with proper surgical treatment may yet recover. It is over this very point that the best type of reeducation breaks down. It is easy to train a patient in substituted or trick movements and to take the result as evidence of recovery, when, as a matter of fact, no sort of recovery of the original nerve lesion has taken place.

3. Enlargement of the Thyroid Gland in Malaria.—J. B. Hume observed enlargement of the thyroid as a complication of malaria—a complication not hitherto recognized—during the East African campaign. His interest was heightened when, in June, 1918, during an attack of malaria, he developed a marked enlargement of the gland himself. The condition is characterized by an acute enlargement of one or both lobes of the thyroid gland during an attack of malaria, and occurring some twelve to thirty hours after the fall of the temperature. In no case of the thirty, all white soldiers, was there a family or personal history of thyroid disease. Malarial parasites were found in the blood in every case, usually in rather scanty numbers. Subtertian forms predominated, but benign tertian and

mixed infections also occurred. In a typical case the enlargement of the thyroid appeared suddenly, in the course of the attack of malaria, from twelve to thirty hours after the fall of the temperature. The previous pyrexia had lasted from one to three days, and no subsequent rise of temperature occurred. One or both lobes became markedly swollen and somewhat painful and tender to touch. There was no redness of the skin, the consistency of the swelling was uniform, and it showed all the characteristics of a generalized enlargement of the gland. Dysphagia, in varying degrees, was a prominent symptom. Pain and throbbing in the head were frequent. There was usually a slight muscular tremor. In only two cases was there any exophthalmos. Tachycardia was very constantly present, the pulse rate being usually in the neighborhood of 100-110, but sometimes as high as 130. Some alteration of the heart sounds at the pulmonary base was common—either a systolic bruit or an accentuation of the second sound. The spleen was enlarged at some stage of the attack in about 70 per cent. of cases. The treatment was usually carried out on routine lines. Quinine buhydrochloride was given by mouth and in a few cases also by the rectum. The usual procedure was to give five grain, three hourly, omitting one dose in the night, over the first four days. Then a smaller dose, 15 to 20 grains daily, combined with arsenic, increasing to the full dose over the relapsing period on the ninth, tenth, and eleventh days. In most of the cases there was, in from four to ten days, a marked reduction of the swelling, but in Hume's own case it had not entirely disappeared at the time of the report. In subsequent malarial attacks it has invariably enlarged for a time. He is inclined to believe, from these and other observations, that the changes in the ductless glands in malaria may be far more marked than present knowledge shows, and that physiological and patholgoical research may show that in these changes may be found the explanation of some at least of the conditions complicating found in malaria.

Correspondenz-Blatt für Schweizer Aerzte.

October 2, 1919, xlix, 40.

Curability of Obliteration of the Central Artery of the Retina.—Strebel relates the following case: woman aged 48 years consulted him in his office on September 19, 1917, for sudden blindness in the right eye. When aged 25 she had had polyarthritis rheumatica followed by a cardiac lesion. There had been no violent exertion preceding the supposed detachment of an embolis from the cardiac interior. There was no history of scotoma scintillans nor headache. Syphilis denied. Four healthy children, no abortions. The ophthalmoscope showed the typical picture of embolism of the central retinal artery. Subjectively there was absolute scotoma for white and colors. Pressure phosphenes were repeatedly obtained. The fellow eye was normal. There was no arteriosclerosis, blood pressure 115. Compensated mitral insufficiency. Urine and Wassermann negative. Treatment consisted of massage of the affected eye and the internal use of digalen, valerian and amyl nitrate. Later the anterior chamber was punctured and pilocarpin given with application of a pressure bandage. By the following October 30 the vision was restored and the objective finds negative. In this case there was simple blocking of the artery without thrombotic process or disease of the vascular wall. The occlusion had been complete according to most of the evidence but this matter must be left undecided because of the absence of disintegration of the blood column. The mere fact of recovery spoke perhaps aganist total obstruction. The possibility of a mere angiospasm can safely be eliminated. The occasion of spasm in migraine in women of the patient's age must of course be borne in mind. The author finds notes of recovery in 14 cases of this embolism.

Peritendinitis of the Achilles Sheath by Metastasis in Tonsillitis.—Rhyiner refers to the frequency of this lesion, which is oftenest due to pressure of an ill fitting shoe or other local external cause. When the foot wear can be eliminated as a cause we see as causal moments strains on the one hand and on the other metastases of a number of diseases as syphilis, gonorrhea, and gout. The condition must not be confounded with bursitis or achillodynia. The author has apparently discovered a new and not uncommon cause in follicular tonsillitis.

La Presse Médicale.

October 4, 1919, xxvii, 56.

Primary Perinephritic Phlegmon.—Bergeret discusses various types of purulent collections about the kidneys. With one we have nothing to do, as it is really retroperitoneal abscess secondary to suppuration in the vicinity, as appendicitis, pancreatitis, etc. There is another type which originates in the kidney itself secondary to tuberculosis and other surgical affections of the organ. With these excluded we can discuss a form which is apparently primary, comes on insidiously and often in the midst of apparent health, and is unrecognized clinically for a long period. This was described by Trousseau who sought diligently but in vain to ascertain its cause. In time we learned the metastatic nature of this lesion and to associate it with an angina or a gastroenteritis or infection of the bronchiopulmonary system. The question comes up "can this affection ever arise without a primary focus?" For the past twenty years we have known that slight foci in the integument have been sufficient to give rise to it. Richardson in an analysis of 108 cases found the following foci: furuncle in 55; felon in 21; local abscess in 11; carbuncle in 10; tonsillitis in 3 and infected wounds in 3. This does not exhaust the list for the following can be added from other sources: parotitis; periosteal abscess, infected mosquito bite, abscess of the rectum and sacrum, osteomyelitis, otitis media, etc. In the vast majority of cases the staphylococcus is the cause, but exceptionally any other pyogenic may replace it. The general disease picture in these cases is due in part to a mild bacteriemia which is not the result but the concomitant of the phlegmon. To this must be added the symptoms due to the latter. The exact mechanism is still obscure, due to the part played by the kidney. In some cases the accumulation of the circulating bacteria near the capsule in the renal vessels is the first stage of the process and this behavior could readily explain the apparent frequency of this accident. But while this type predominates it is none the less true that the kidney is sometimes intact. These cases are rare and due to the direct deposit of the coccus in the perirenal fat. In the renal type conditions then do not differ radically from the metastatic abscesses of the kidney in acute sepsis? The very frequent presence in the urine of the staphylococcus is of diagnostic utility.

Finska Läkaresällskapets Handlingar.

September-October, 1919, lxi, 9 and 10.

Etiology of Appendicitis.—Sandelin finds that the bacteriological explanation of this affection is not entirely satisfactory, for the disease may happen without evidence of infection. Further, infection does not explain all of the pathological alterations, such as gangrene of the appendix tip with the remaining organ intact. The presence of fecal concrements in the nonstrictured appendix is also difficult of explanation from this viewpoint. As a result of study of many appendixes which were not dislocated, the author is inclined to see a disease process determined entirely by anatomical and mechanical factors. The process may originate as a result of malformation either of the organ itself or its mesentery—malformations either congenital or acquired. These act simply by causing retention or occlusion. The lowered nutrition may invite bacterial invasion, but the microorganisms are preexistent in the appendix. If the occlusion disappears in the process, or, in other words, if there is drainage, we have a harmless and self-limited attack, but if it develops or persists we see develop gangrene or perforation. In the noninfectious case occlusion leads merely to dropsy or sterile empyema of the appendix. Incomplete retention makes possible the formation of concrement, and incarceration of a concrement will determine an acute crisis. Transitory and incomplete occlusion causes chronic inflammation as a secondary manifestation.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Thirteenth Annual Meeting, Held at Asheville, N. C., Nov. 10, 11, 12, and 13, 1919.

THE PRESIDENT, DR. L. F. BARKER OF BALTIMORE, MD., IN THE CHAIR.

Scientific Teamwork in Diagnosis and Treatment of Diseases of the Eye, Ear, Nose and Throat.—Dr. E. M. CARY of Dallas, Texas, said that group practice was desirable whether it be from the point of view of a surgeon dominating the situation, a medical man, or an ophthalmologist. In recent years he had grown to devote from four to six hours, as a morning's work, in an operating room in a general hospital where every possible means for concluding a diagnosis and every facility for operating was provided. There was a trained anesthetist, a graduate in medicine, who limited his activities while he was in the hospital to his service, and, although he had interns and a well-organized training school, the hospital provided a graduate nurse who had complete charge of all the details in the operating room. There was an associate who reached the hospital at an early hour, and who saw that the patients were properly classified and placed. The operations were planned in a way that all the clean cases were taken care of first and the others afterward.

The Treatment of Visceroptosis.—Dr. F. W. WILKERSON of Montgomery, Ala., stated that the chief factors in the production of the acquired type as given by Kemp were (1) various skeletal deformities, such as spinal curvature, rickets, kyphosis and kyphoscoliosis; (2) intrathoracic pressure on the diaphragm from effusions, tumor, etc.; (3) intraabdominal tumors of leukemic enlargement of the spleen; (4) chronic dilatation of the stomach; (5) adhesions attached to movable viscera; (6) compression of the thorax by tight lacing, poor corsets, etc., and (7) relaxation of the abdominal muscles and consequent diminution of intraabdominal pressure. Fairly marked grades of visceroptosis might exist without the production of symptoms and, on the other hand, severe symptoms might result from slight ptosis. This was probably a result of the underlying condition and depended, too, on whether or not there was interference with the motor functions of the gastrointestinal tract. For purposes of treatment the cases might be classified as (1) those which could be given ambulatory treatment and (2) those which required a preliminary period of rest in bed. The general principles of treatment were followed in both cases, the mild cases coming within the first class, the severe ones in the second. All cases of visceroptosis could not be cured, but about two-thirds could be given permanent relief and the other one-third temporary relief. This meant much to a large class of sufferers. The condition was so easily recognized and could be so readily treated that it was a great pity more attention was not paid to it by the majority of the profession. The difference between a case before and after treatment was striking. Most of the nervous symptoms were gone, the patient felt stronger, more energetic, had a better appetite, a more cheerful outlook on life. He could do his work with comparative comfort and was more grateful for his improvement than people with almost any other condition of which the speaker knew.

The Intestinal Protozoa; Methods of Diagnosis and Treatment.—Dr. S. K. SIMONS of New Orleans said that in only one instance did we possess a specific remedy against intestinal protozoa. The various morbid conditions which developed as a result of the penetration of the entameba histolytica into the tissues were promptly controlled by the use of ipecac or its alkaloid constituents. Emetin merited a high place in the treatment of the acute or active phases of all forms of entamebiasis, but could not be depended upon for the complete clearing of the intestinal tract in chronic cases. For this purpose the writer believed that the entire powdered ipecac root was needed. This drug must be administered, however, daily in full concentrated doses covering a period of from ten days to two weeks. If given by mouth in one dose in the form of enteric coated pills, the ipecac could be made to reach the large bowel, where absorption took place directly within the confines of the disease-producing area. In the past few years the introduction of transduodenal lavage by the Jutte method, it was thought, might offer new hope for the removal of intestinal protozoa. This plan constituted in effect the irrigation of the entire intestinal tract from above down with a hypertonic or unabsorbable salt solution. Unfortunately the early optimism in regard to this method had not proved justifiable, as the writer had convinced himself from numerous and repeated observations.

The Effect and Maintenance of Intraabdominal Pressure.—Dr. J. B. FITTS of Atlanta emphasized the following principles: (1) Normal intraabdominal pressure was a necessary physiological entity; (2) low intraabdominal pressure was a factor in general physical inefficiency; (3) it was of particular importance in disease of the gastrointestinal tract; (4) it could be maintained by the application of physiological principles.

Concerning Focal Infection.—Dr. THOMAS D. COLEMAN of Augusta, Ga., said that in the treatment of cases of focal infection it was essential that (1) the focus or foci should be removed where the end justified the means, and one should keep in mind the possibility not only of not doing good, but also of doing harm "non nocere"; (2) every agency both in building up the bodily defenses and ameliorating symptoms as they arose should be employed; (3) to all those who leaned to radicalism, he would suggest a motto, "Festinate lente." The following were his conclusions: "1. The fact of focal infection is not disputed. 2. Focal infection is caused by pyogenic organisms that are distributed through the body by means of the blood and lymph streams. 3. Foci of infection, when removable, should be removed, but that removal should be a treatment and not a diagnostic procedure."

Lesions of the Fifth Cranial Nerve in Connection with Auditory Vestibular Disturbance.—Dr. E. R. CARPENTER of Dallas, Texas, thought that the otologist should never be contented with making a diagnosis of nerve deafness, but he should determine whether or not the lesion was of intracranial origin. The prognosis and treatment depended on this point. The neurologist or brain surgeon might not be consulted until the disease had advanced too far to prevent deafness or loss of life, as often occurred with tumors, abscess, syphilis, circulatory disease, toxemia, etc. In Cushing's book on "Tumors of the Auditory Nerve" the sad fact stared us in the face that in every one of his thirty-five cases the first symptoms were disturbance of hearing, yet all of them came to him in an almost hopeless condition, being either paralyzed, blind, or nearly blind, or they had some other equally as serious complications which rendered the operation exceedingly dangerous and the prognosis serious even if they survived the operation. In most all of these cases an early diagnosis would have offered a very good chance to have escaped the terrible complications and to have saved many lives. The author's summary was that the otologist was not required to make absolute diagnosis of intracranial disease, but auditory-vestibular diagnosis had been developed until we could usually determine whether or not we were dealing with an intracranial lesion. This ability entailed some knowledge of the other cranial nerves and the object of this article was to call particular attention to the importance of carefully considering the fifth cranial nerve in auditory-vestibular investigation.

Intranasal Surgery Without Packing.—Dr. WILLIAM T. PATTON of New Orleans asked the question, "What were the advantages of leaving out packing? (1) Greater comfort to patient, who often was able to breathe through the nose continually. (2) Much less reaction to disease in the nose; usually twenty-four hours after operation, if clots were clearing out of the nose, it was surprising to see how little reaction remained. (3) There really seemed to be less bleeding without packing in most cases—that is, provided the adrenalin spray was used, cold compresses, and the patient kept in the reclining position. Occasionally a hematoma occurred between the flaps. However, this was rare if a counter opening was made near the floor of the nose. If it did occur, it was a simple matter to curette and again seal flaps. Apply compound tincture of benzoin. A few cases bled

more freely than we would like and it might become necessary to pack. Again no harm was done.

Vincent's Disease.—Dr. JOHN J. SHEA of Memphis drew the following conclusions: "(1) Vincent's disease is a degenerative condition and not an inflammatory condition. (2) A smear should be made and studied of every acute throat and gum disease and not all the reliance be left to a culture. (3) Medicinal treatment is only temporary and surgical intervention is indicated for permanent relief. (4) To make the infection reportable and in armies, schools, and institutions to consider it contagious and quarantine. (5) Always work in conjunction with a competent dentist."

Radical Mastoid Operation; Indications.—Dr. ELBYRNE GILL of Roanoke, Va., drew the following conclusions: "(1) The radical mastoid operation is not indicated in all cases of chronic aural suppuration. (2) It is possible to get dry cavities in most cases. (3) The hearing in the average case should be improved (4) With proper technic the operation is not dangerous. (5) The condition calling for operation is usually a very dangerous one and it is too frequently dealt with lightly."

Comparative Study of Gastric Motility as Determined by the Ordinary Test Meal and Six-Hour Barium Retention.—Drs. HARVEY G. BECK and JOHN EVANS of Baltimore stated that their observations indicated that frequently in adhesions involving the pylorus and duodenum the power of the stomach to empty itself was, at first, increased and later diminished. The degrees of gastric acidity seemed to have little or no influence upon the amount of gastric contents after test breakfast or six-hour retention. No interpretation should be made on this point without studying the acid curve by Rehfus' method of fractional gastric analysis. A discussion of the motor mechanism of the stomach and the factors influencing this function had been purposely omitted, since it did not come within the scope of the paper. The results of these studies might be summarized as follows: "(1) The motor function of the stomach can be determined by the complete removal of a standard test meal with the partial vacuum method. (2) There is no constant relation between the motor function, as determined by the test meal method and six-hour barium. (3) Six-hour barium retention occurs after a motor meal if the stomach contents exceed 200 c.c. in fifty minutes, or 150 c.c. in sixty minutes. (4) The comparative results of the two methods are most uniform and constant in duodenal ulcer. (5) Six-hour barium retention occurs more frequently in adhesions involving the pyloroduodenal region than in either duodenal or gastric ulcer. (6) There is very little evidence to show that the secretory function has any influence on the motor function in pathological conditions affecting the stomach and duodenum."

Some Considerations in Interpreting Muscular Imbalance.—Dr. HIRAM WOODS of Baltimore read a paper on this subject. He summarized as follows: "(1) The meaning of muscular imbalance cannot be determined by the balance test alone. (2) Functional force of muscles should be determined by their power to overcome prisms. (3) Owing to the close relation between accommodation and convergence prism strength must be regarded as the extent to which this separation is possible, not as indicating the intrinsic power of the interni. (4) In horizontal heterophoria the basis of calculation should be divergence power (abduction) because of the single nerve supply of the externus. (5) The minimum of abduction should be 5°, the minimum of positive relative convergency about 3° to four times as great. (6) The vertical recti should practically balance each other at 2½° to 3°. (7) In prescribing prisms for constant wear the muscle to be helped should be weaker than normal and its antagonist stronger, otherwise there is danger of converting one form of heterophoria into another."

The Signs and Symptoms of Hypopituitarism.—Dr. STEWART R. ROBERTS of Atlanta said that undergrowth, dwarfism, dysgenitalis, feminine hirsuties, feminine type skeleton, lack of secondary sexual characteristics, genital atrophy and impotence, headaches, languor, weakness might appear in varying degrees in different cases at different periods. The classical signs and symptoms of hypopituitarism were subnormal temperature, dry skin, adiposity, low blood pressure, slow pulse, constipation, amenorrhea, drowsiness, and inactivity. Lack of attention, impairment of memory, actual dullness, mild psychoses, to actual convulsive seizures with epileptic attacks might occur. The cause might be glandular deficiency of one or both lobes, a pituitary tumor with damage of the gland, a neighborhood tumor or hydrocephalus with pituitary pressure. The symptoms of intracranial tumor might be more prominent than those of pituitary deficiency. Infantilism, dysgenitalism, obsity, symptoms of intracranial tumor, warranted pituitary study.

The Responsibility of Physicians Who Treat Malaria Cases.—Dr. C. C. BASS of New Orleans stated that the important duties or responsibilities of physicians who treated malaria cases were: (1) To begin promptly proper treatment with the specific remedy for the disease, quinin, not neglecting it for spectacular methods of treatment. (2) To advise the patient of the proper diagnosis and nature of the disease. (3) to advise him of the mode of transmission of the infection and of the great danger of transmission to other members of his family and associates, endangering their health and perhaps life. (4) To advise and prescribe specific treatment which would disinfect the patient so as to avoid relapse and prevent transmission.

Coccidioidal Granuloma.—Dr. KENNETH M. LYNCH of Charleston, S. C., said that no successful treatment had been devised and all cases save one had died within from a few weeks to nine years. The only case recovering was one in which the infection was recognized in an extremity and the infected member amputated apparently before dissemination had occurred. The first case of coccidioides immitis infection in South Carolina and east of the Mississippi, it being the forty-fifth case, the second case in a woman, and the fourth that had not been in California, was reported. The confusion of the disease with tuberculosis had again occurred, even though a complete investigation of the case would no doubt have revealed its true nature. The parasite should have been found in the sputum and urine. Again we were reminded that even in medicine things were not always what they seemed, and no diagnosis on circumstantial evidence could be positive. The failure to use methods and means which were at hand for diagnosis, no matter how apparently clear the case might be, was inexcusable. It was highly probable that infection by coccidioides immitis was with us where we had not recognized it, and it was desirable that those cases of supposed tuberculosis in which the tubercle bacillus was not demonstrable should be carefully investigated for this or kindred infection.

Simplified Technique for Local Anesthesia of Tonsils.—Dr. W. T. PATTON of New Orleans stated that it was remarkable how easy one might anesthetize the tonsil in this way with a small quantity of fluid and only one or two punctures. If the tonsil was large or long, it was best to make two punctures—one through the upper and one through the lower pole. It might be said that there was danger of causing infection by going through the tonsils. Of course this was possible in all injections. In over 500 cases he had never had any deep infections. He had removed and seen removed some 500 tonsils by this method of anesthesia and had had excellent anesthesia in practically all. The advantages were: (1) Excellent anesthesia; (2) small amount of fluid injected into tissues; (3) lack of edema and disturbance of tissues; (4) lack of postoperative reaction.

The Status of Amebic Dysentery with Special Reference to Diagnosis and Treatment.—Dr. RANDOLPH LYONS of New Orleans said that probably the very latest treatment with the newest remedy on the market was the use of benzyl benzoate in dysentery. Macht and Fisher believed it had amebicidal qualities based on a series of experiments *in vitro*. Its clinical use was reported by Houghwout and Lantin. They treated eight cases (including Osuzanos two cases), which were all benefited. The dose was 10 to 30 drops three times daily. The cases had not been followed long enough to make any definite statement as to cure. Many other drugs and methods of treatment might be mentioned, but they appeared to be of minor importance and their value problematic. In briefly summing up the various methods of treatment advocated at the present time, one could safely state that ipecac and its alkaloids were still the sheet anchor in the treatment of amebic disease. The tendency of the times was to administer a combi-

nation form of treatment—that is to say, emetin hydrochlorid was given hypodermically in conjunction with the oral administration of either emetin hydrochlorid, powdered ipecac or emetin-bismuth-iodid. Occasionally some other drug might be administered by mouth as Chaparro or bismuth. There was reason to believe that this form of treatment was a distinct advance in the therapy of amebic dysentery and that by its use relapses would be markedly diminished. It had met with notable success in the treatment of carriers.

Subacute Combined Degeneration of the Spinal Cord.—Dr. WILLIAM G. SOMERVILLE of Memphis drew attention to the similarity between the nervous symptoms of subacute combined degeneration of the spinal cord and pellagra. Both diseases had in common secondary anemia, gastrointestinal disturbances, degeneration of the posterior and lateral columns of the cord, pigmentation of nerve cells and frequent occurrence of mental symptoms. One of the chief points of difference was the presence in pellagra of the characteristic skin lesions, which, it was agreed, were due to the trophic disturbances from involvement of the spinal ganglia—that is, the extension of the foci of degeneration into the posterior nerve roots and their ganglia. The secondary anemia was common to both, but more intense in the subacute combined degeneration and more likely to assume a pernicious type. The cercomonas intestinalis hominis had been found in the intestinal discharges of both; in every case of pellagra, according to Jelks, and in the case of subacute combined degeneration reported in the paper. It was very evident that one case proved nothing, but this statement was made as a preliminary to further investigation, and to call attention to the very great importance of examination of the intestinal discharges of these patients as well as of a careful comparison of the clinical signs and pathological findings in these two types of disease. For, after all, we might find they were one and the same, and all their symptoms produced by a common cause, an intestinal parasite.

The Minnesota Rural Clinic.—Dr. E. J. HUENEKENS of Minneapolis stated that the value of these clinics consisted in: (1) The teaching of the proper feeding of infants and children, and the especial value of maternal nursing. (2) General hygienic instructions, the value of fresh air, sunshine, and proper clothing. (3) The early recognition of defects before they were obvious to the parents. (4) The awakening of general interest in child health and child welfare. (5) Last, but not least, the education of physicians.

Hookworm and Manifest Tuberculosis.—Dr. ROY D. ADAMS of Washington, D. C., stated that while hookworm disease and tuberculosis were often referred to in the literature as being related, and though the inference was frequent that the connection was one of cause and effect, no serious studies had been made which placed the relationship on anything firmer than a speculative basis. Available sources of information indicated that manifest tuberculosis was more frequent among individuals harboring hookworm than among the hookworm free, living under similar conditions. A generally lowered resistance, incidental to hookworm disease, especially evident as anemia and malnutrition, was credited with being the essential factor producing lapse of immunity to tuberculosis. There was no evidence establishing any specific relationship between the two diseases. Inasmuch as it had been demonstrated that the mortality from tuberculosis might be reduced by a measure so simple as the elimination of hookworm where double infection existed, the obligation of the physician with regard to diagnosis and treatment was apparent.

Empyema: Recent Experiences.—Dr. FRANK K. BOLAND of Atlanta stated that making the earliest possible diagnosis of acute empyema was a burden which fell on the general practitioner, the pediatrician and the internist, who must ever be ready with the exploring needle. How often had pus in the chest been called unresolved pneumonia for so many days or weeks that the condition was already chronic before its presence was known? No one could deny the advantage of having pus run through a tube into some kind of a receptacle instead of keeping the dressings soaked. Suction should be applied to such a tube, if an efficient means was provided. The use of Dakin's solution was not advised immediately following the opening of the chest in acute empyema. A few days later, when the abscess had had time to become well walled off, and there was no danger of a bronchus communicating with the cavity, Dakin's solution might be tried. The last word in the treatment of empyema had not been said. Much had been added to our knowledge concerning it through recent experiences. Every thoughtful effort to decrease the mortality and shorten convalescence should be encouraged and given a fair chance. However, until new methods had been tried in a sufficient number of cases and over a long enough period to insure their worth, it was safer not to depart too far from paths that were beaten and true.

The Medical Profession in the War; Its Sacrifices and Compensations; Humanity's Gains.—Dr. JERE L. CROOK of Jackson, Tennessee, said that as shown by the experience of the best men and reported by them in the medical literature during and since the war, surgery's outstanding gains might be summed up as follows: The Carrel-Dakin method of treating suppurating wounds. A revival of the use of debridement, first used extensively in the Napoleonic wars. The treatment of shock caused by hemorrhage with blood transfusion by the citrate method, demonstrating the great superiority of blood over salt solution, because the former had real sustaining power and the latter was temporary only because osmosis soon carried it out of the vessels. The paraffin treatment of burns. Improved methods in the treatment of fractures and the use of the Thomas and Blake splints and the Balkan frame. Early mobilization of injured joints. Management of lung injuries. Improvements in plastic surgery. Reeducation of the crippled.

Toxic, Nonexophthalmic Goiter.—Dr. WILLIAM D. HAGGARD of Nashville said there were several reasons aside from accuracy why this type of goiter should be more generally recognized: (1) It was quite as dangerous, if not more so, than exophthalmic goiter, because the toxin seemed to have a selective action upon the heart, causing the so-called "goiter heart," thyrotoxic, instead of the mechanical "goiter heart," from pressure. (2) It was more apt to be overlooked on account of the absence of exophthalmos and the gravity of impending heart symptoms, not appreciated. (3) Many adenomas, so simple of surgical cure as such, were prone to degenerate and produce toxic symptoms. (4) The long duration of an atoxic goiter before producing toxic symptoms and the belief of its perpetual innocence by the physician and patient. (5) The danger of administration of iodin in goiter of long standing and its proneness to set up toxic and sometimes fatal symptoms. (6) Frequency of toxic, nonexophthalmic goiter was one out of four goiters that were not hyperplastic. Sometimes an operation on a long standing goiter for pressure symptoms, which might be supposed to be "the head of front of the offending," would be carried out brilliantly from a technical standpoint, only to find that the patient would go out suddenly and unexpectedly from a fatally damaged myocardium that was not or perhaps could not be detected beforehand. Operation was surgically the right thing at medically the wrong time. It was probably from fifteen to thirty-five years too late. Toxic goiter was not definitely improved by ligation, as was exophthalmic goiter, which gave marked improvement in exophthalmic goiter, and an average gain of over twenty pounds following it within three months. It was not generally realized that operation for toxic goiter was quite as dangerous, if not more so, than in the exophthalmic type. It was not due to the technic but to the condition of the patient. In his last series of 100 toxic cases, exclusive of the so-called simple goiter, 2 deaths occurred in 33 operations for toxic, nonexophthalmic goiter and only 2 in 67 exophthalmic cases.

Nonhypertrophic Forms of Prostatic Obstructions.—Drs. BRANSFORD LEWIS AND NEIL S. MOORE of St. Louis felt that from a study of their cases the following conclusions could be deduced: (1) Nonhypertropic obstruction at the bladder neck is a definite pathological condition, appearing at any age, but most common in later life. (2) Its diagnosis is practically easy providing a systematic examination is made. (3) Of the different points in the examination, probably cystoscopy is the most important. (4) We feel that the treatment

used is very simply, easy to do, if done properly. The patient does not have to go to the expense or spare the time of an open operation. The risk is comparatively small, and the results in appropriate cases have been very satisfactory.

Treatment of the Acute Abdomen.—Dr. J. P. RUNYAN of Little Rock stated that after a careful study of his results and of the answers to a questionnaire sent to a number of prominent surgeons in different parts of the United States, he had formulated the following conclusions: (1) It is a safe and sane procedure to operate early in the attack of acute suppurative peritonitis. (2) After the stage of contamination comes the stage of diffuse peritonitis in which the Ochsner treatment offers the largest percentage of recoveries. (3) The exceptions to rule 2 are perforation of duodenal ulcer and gunshot wounds of the hollow viscera. (4) Do not get in too big a hurry to operate once the Ochsner treatment has been begun. (5) Following the Ochsner treatment operation should be done and Crile's principles applied in the after-treatment of all cases of septic peritonitis. (6) Where there are large areas of denuded peritoneum, from which may be expected a considerable flow of pus and serum, gauze drainage after the manner of Mikulicz or Price may be expected to give the most satisfactory results. (7) In cases in which no peritoneal denudation has occurred rubber tube drains will suffice.

Malignant Moles.—Dr. H. H. HAZEN of Washington, D. C., stated that prevention was better than cure Every acquired mole should be removed, preferably by cautery. Every congenital mole which was liable to irritation should likewise be removed by the same method. Whenever a mole began to grow or to show signs of either irritation or ulceration it was an imperative sign for immediate extensive operative interference, preferably with the cautery, though this would often be too late. When numerous metastases had appeared treatment was useless. In the cases where involvement was only in the lymph nodes extensive block dissection might occasionally effect a cure. He knew of two such cases which had been well nearly six years following intensive Roentgen ray therapy.

The Use of Radium in Gynecology.—Dr. WILLIAM C. GEWIN of Birmingham drew the following conclusions: (1) Radium is the treatment of choice (*a*) in cases of menorrhagia of the menopause not associated with large fibroid tumors, and in which the possibility of carcinoma has been definitely eliminated; (*b*) cases of menorrhagia in patients between the ages of 35 and 40 years of age who have small sized mucous fibroid tumors with no demonstrable evidence of malignant conditions existing; (*c*) cases of myomas in which there is a contraindication to operation; (*d*) cases of menorrhagia in young persons who have resisted all medical treatment. (2) In all cases with a malignant tendency. (3) In all operable cases after a complete surgical extirpation of all cancer possible as a prophylactic, and also to destroy such cancer cells as are not possible to be removed by the surgeon. (4) In all inoperable cancers of the uterus radium will relieve pain, eradicate the offensive odor from the discharge and stop the hemorrhage, and in many cases produce an anatomical and symptomatic cure when the patient seems to be moribund. (5) Radium will render operable many cases that are inoperable. (6) The use of radium is practically the only means of relief in cases of recurrent carcinoma of the uterus. (7) In the use of radium it is very essential that one have a thorough knowledge of the technic of its application and of its physical properties as modern scientific research has given to the profession.

The Value of Radium in the Treatment of Bladder Tumors.—Dr. J. T. GERAGHTY of Baltimore stated that while benign and malignant papilloma and the early papillary carcinoma disappeared under the influence of radium the infiltrating types had proven very resistant to this agent. It was his procedure, therefore, when the infiltrating character of the growth had been determined and when the tumor was sufficiently localized to permit of complete removal, to carry out a radical resection. Following the removal of an infiltrating papillary carcinoma, cystoscopy should be done at an early date as the not infrequent recurrences yield promptly in many instances to radium, notwithstanding the resistance of the primary tumor. It was of interest to note that the use of radium had not diminished the tendency of bladder tumors to recur, recurrences being observed in about 30 per cent. of the cases treated. The recurrence, however, responded to radiation in most instances, although in three cases it did not yield. Radium had certainly proved to be a valuable aid in the treatment of bladder tumors and while the results obtained in the infiltrating types were far from satisfactory, improved technic whereby more intensive radiation might be safely accomplished might offer a more encouraging outlook in the future handling of these cases.

Pulmonary Syphilis.—Dr. J. H. GIBBES of Columbia, S. C., reiterated the following ideas: 1. A chronic pulmonary disease, physically indistinguishable from the common types of chronic pneumonitis, and producing a symptomatic picture similar to that of pulmonary tuberculosis, was not infrequently associated with a positive Wassermann reaction, and the favorable change in general and local conditions following antisyphilitic treatment was so striking as to lead one to the opinion that the syphilitic process was, at least, in part, responsible for the pulmonary pathology. 2. A Wassermann reaction should be a routine in the investigation of all chronic pulmonary diseases, even though the tubercle bacillus or other organisms be found in the sputum.

Ileocolitis.—Dr. N. C. WOMACK of Jackson, Miss., stated that ileocolitis was mainly due to a gas producing bacterium and, in his opinion, this bacterium was an attenuated or malignant form of the colon bacillus. Second, that there was always an attending pyelitis in which the colon bacillus in great numbers was found and that this pyelitis might antedate and certainly was the immediate complication of ileocolitis, and assumed the major role from the standpoint of the cause of death. Third, in the treatment of ileocolitis first attention should be paid to the kidney. Fourth, forced feeding of a selected carbohydrate diet with plenty of water should be given. Fifth, all forms of rectal irrigations or alimentation should be strictly interdicted on the ground that they not only did no good, but were distinctly harmful.

Some Facts and Fallacies Relating to Maternal Feeding of Infants.—Dr. J. D. LOVE of Jacksonville, Florida, said that in the field of medical practice probably more frequently than elsewhere were serious errors made in connection with (1) premature withdrawal of the infant from the mother's breast, (2) conclusions from laboratory examination of breast milk, and (3) dieting of the mother to overcome defects in her milk supply. As concerned the mother's dietary, the only general rule he knew, susceptible as it was to some modification, was that it should consist of food generous in quantity, easily digested and above all, a food to which she was accustomed. We might regard it as axiomatic that a food that caused indigestion in the mother would cause trouble for her nursing baby. And, on the other hand, if a mother could well handle even the most indigestible food, her baby would rarely suffer in consequence. The gross appearance of breast milk furnished but an unreliable index as to its suitability for the baby. Before pronouncing the milk as being too rich in quality, the presence or absence of colostrum bodies should have been determined by microscopic examination. The mere fact that the milk was scant in quantity furnished no valid excuse for the withdrawal of the infant from the breast, but rather called for supplemental feedings. Conclusions drawn from chemical examinations of breast milk, as usually practised, were apt to be misleading. Laboratory findings should be confirmatory of clinical observation. In influencing the quality of breast milk the maternal dietary, while of some importance, was a smaller factor than causes which operated through the medium of the mother's nervous system.

Acute Infections of Childhood.—Dr. R. M. POLLITZER of Charleston, S. C., stated that notwithstanding some recent excellent work the causative factor of measles had not been found. Until it was we should have to postpone the solution of many of its problems. But clinically the diagnosis was easily made before the rash. This early diagnosis was most important for the safety of others. Our great field here would seem to lie in the education of the people first that measles was most

contagious before the eruption, and that it was a very serious disease, especially in early childhood. The most important point in the management of the case was close attention to ears, mouth, and lungs. It had been well said that whooping cough was a disease, the mortality from which entitled it to more serious consideration than it usually received from physicians and parents. In 1918 alone, 224 children died from it. Because the disease at its onset was only a cough, and throughout its course usually did not necessitate being in bed, there was a most excellent method of spread. The patient did not have to wait for the approach of his victim, but went in search of him. It was the common practice to advise keeping the child in the open as much as possible, but it was uncommon to caution against going near others. We must sharply differentiate, however, between the use of a vaccine as a means of prevention or of cure. It was true enough that, at times, where it was begun as a prophylactic we realized after the first or second doses that the disease was present already. Nevertheless it might be used in well children before exposure or before the onset as an immunizing agent. The reports as to its efficacy were quite varying. In a few cases he had employed the vaccine in well children who had never had the disease. Subsequently they were unintentionally exposed and did not contract it. Notwithstanding the finding of a diphtheroid bacillus in the throat of scarlet fever patients by Mallory in 1916, as yet we lacked sufficient evidence. Unlike many other of the acute infections, aside from the clinical phenomena, our knowledge in this disease was very incomplete. We were not even sure that it had been transmitted to monkeys. There was not a single drug that had the least effect in modifying its course. It had a greater variability in its virulence than most diseases excepting influenza and infantile paralysis. We knew that it was not nearly so contagious as measles and whooping cough, notwithstanding the popular belief. Unlike scarlet fever there was unfortunately nothing alarming in the onset of diphtheria. The average individual judged of the severity of any disease by the amount of fever or pain present. The fact that diphtheria frequently gave rise to less constitutional disturbance at least for several days than the ordinary tonsillitis was undoubtedly responsible for many deaths. When asked what medical science had accomplished for humanity we could point with pride to what had been done in diphtheria. Our knowledge here was more complete than in any other disease. Beginning with the discovery of the organism way back in 1883, the introduction of the serum in 1893, and finally the Schick intracutaneous test for immunity in 1915, we had made great strides in the conquest of this once dreaded disease, which even as late as 1889 was written of by J. Lewis Smith as "one of the most fatal and unfortunately one of the common maladies of childhood." There were fewer unsolved problems in diphtheria than with most of the other infections. By the use of the Schick test we had learned the percentages of immune people at different ages. Further in individuals we knew who had sufficient natural antitoxin to prevent the acquiring of the disease under ordinary conditions.

Otitis Media.—Dr. Lawrence T. Royster of Norfolk, Va., said that otitis media might occur with fever and without pain, or with pain and without fever. The former was more frequent in infancy and early childhood, while the latter was more apt to occur in later childhood; though temperature was also frequent here, yet notable exceptions to this general rule were common. It could not be emphasized too strongly, that it was an error to suppose that because a child had not an earache, there was no middle ear inflammation. In Norfolk the first outbreak of influenza affected comparatively few children, while during the second, which occurred after quite a lull in morbidity, a comparatively larger number of children were affected. In both outbreaks the incidence of otitis was large. The phase of otitis media which he wished to emphasize on this occasion was the variety and manifestation of inflammation of the middle ear, the tympanum and the mastoid cells, which routine examination of the ears of all children coming to our attention presented. The treatment of otitis media, uncomplicated by mastoid involvement, was comparatively simple, though the results were by no means always gratifying. He could see no rational reason for treating an otitis media by applications to the drum through the external auditory canal. Such applications might relieve pain temporarily, but he failed to see how they could do permanent good, since in the majority of instances there was pus in the middle ear. Some otologists claimed that some inflammations subsided under this procedure; we also knew that many cases subsided without any treatment, and he was quite sure he had seen more cases which were treated in this way eventually require an incision than he had seen cases subside under this treatment. He might appear somewhat radical in his ideas as to treatment, but he believed that most pediatricians agreed that uniformly red drums, even without bulging, should be incised. In so many instances we found pus on incision in cases in which there was redness, even without bulging, that he felt it was better to be on the safe side. When seen early, and when we had an opportunity to watch the cases closely, we might temporize. Of course, there could be no doubt that many inflamed membranes resolved without rupturing. We had all seen ear drums with marginal redness, or little fan-like or wedge-shaped areas of inflammation, spreading towards the center, followed by general redness, which resolved in a short time. On the other hand, we had also examined drums with marginal redness only, which ruptured and discharged pus before an examination on the next day. In cases of slightly red membranes it had been his custom to use nose drops of menthol, camphor and white oil, with the idea that such a mixture contracted the swollen mucous membrane at the inner opening of the Eustachian tube, and thereby promoted drainage of the middle ear. When cases of middle ear inflammation were accompanied by tenderness over the mastoid cells it was generally agreed that the drum should be cut.

Treatment of Enterocolitis in Infancy.—Dr. W. W. Harper of Selma, Alabama, said that the indications for treatment were: (1) Prompt cleaning of the intestinal canal by catharsis and enema. (2) Withdrawal of all food for 24 to 48 hours. (3) Sowing intestinal canal with virile strains of lactic acid bacilli. (4) An abundance of water by (*a*) mouth, (*b*) rectum, and (*c*) hypodermoclysis. (5) Free administration of alkalies and, if acidosis threatened, the use of carbohydrates. (6) Adopting measures to prevent urinary suppression. (7) Early return to the breast or bottle. As an initial purge, the writer preferred castor oil. If the first dose was vomited, a second dose was given at once, and if this was vomited, a third dose was given. From the three doses sufficient oil would be retained to act. A soda enema (two teaspoonsful of soda bicarbonate to a quart of warm water) was given every six hours for the first 24 to 48 hours. These enemas not only cleared the bowels of foul feces, but they furnished water and alkalies to the tissues. All food was withdrawn at once and water forced—the minimum amount of water to equal the amount of milk taken in health. When the infection was mainly confined to the colon as evidenced by blood, jelly-like mucus and tenesmus, the above treatment was carried out with some modifications. After the initial purge, paregoric was given to relieve pain and to diminish the frequency of stools. Give enema only once a day, as frequent enemas irritated the bowel and disturbed the patient. For tenesmus, and to hasten the cure, nothing had served the writer so well as an enema of silver nitrate solution, one-half per cent to one per cent in distilled water. The technic was as follows: The bowels having been flushed with sterile tap water, 8 ounces of silver solution was allowed to run into the colon through a large catheter. While the patient was straining to pass this back, the mucosa of the rectum was painted with silver nitrate, 12 per cent., the whole painted area being neutralized by allowing a strong solution of sodium chlorid to flow through the rectal catheter. This gave marked relief.

Aneurysms.—Dr. Edward B. Anderson of Chattanooga stated that the patient's history, his radial aneurysm, the hemorrhage in the liver, the gangrene in his toes and later his leg, caused by general arterial disease, made it almost certain that the hemorrhage in the liver must have been the result of a rupture of a small aneurysm of one of the branches of the hepatic

artery. The fact that it occurred in the substance of the liver, and that it was controlled by parenchymatous sutures (two mattress sutures) and a gauze pack, would indicate that only a peripheral branch was involved. This was the rare and exceptional feature of the case, because while the literature of hepatic aneurysm was rich in the reports of cases in which the main artery or its branches had been involved, the aneurysms had rarely, if ever, developed in the hepatic substance where the vessel was well supported by the prolongation of Glisson's capsule. Of course, whether the hemorrhage was the result of a rupture (probably miliary) of the aneurysm or of a simple breakdown of an atheromatous artery, had not been determined. While the hepatic artery, or its branches, had been ligated eleven times, there were only two cases in which this ligation was done for aneurysm of the artery or its branches.

Injuries of the Spleen, with Report of Four Cases.—Dr. E. B. CLAYBROOK of Cumberland, Maryland, said that the two most significant symptoms that he had noted were, absence of peristalsis, and the transmission of the heart and respiratory sounds, so that they might be heard all over the abdomen. These, of course, did not especially indicate splenic injury, but did indicate injury in the abdomen, and with a proper history, would often be sufficient to prompt a presumptive diagnosis of splenic injury. In the second case here reported, the only sign of internal injury was a slight tenderness in the left flank with transmission of the heart and respiratory sounds, and with these present, in spite of the fact that the man had suffered a crushing off of the left leg below the knee, he felt that it was not safe to attribute his shock and anemic appearance to the leg injury—so first made an abdominal exploratory incision, and found the spleen torn from the bottom, up through the hilus, with the abdomen filled with blood. Had the leg been amputated, the patient put to bed without further examination of the abdomen, he would have died promptly, and the death attributed to shock following amputation of a crushed leg. The treatment must be prompt laparotomy and removal of the spleen, if it was much lacerated; as these patients had already lost a quantity of blood and if we depended upon packing or suture, we were running a risk of recurring hemorrhage that he felt was not justifiable. Then, as a rule, splenectomy could be done quicker, and with less operative trauma, than packing or suture.

Surgical Intervention of Acute Intracranial Injuries.—Dr. YOUNG C. LOTT of Atlanta stated that intracranial injuries should have free catharsis, preferably magnesium sulphate, ice caps to the head, and above all, absolute rest. Chloral and bromides might be used per rectum for sedatives but not morphine, for then respiratory conditions were interfered with. Atropine, grain 1/15 hypodermically, might be used for beginning edema of the lungs and medulla. Forced fluids, avoidance of excessive stimulation, but warmth and coffee per rectum were excellent to revive patient from shock. Absolute rest was most essential, even more so than any other known medicinal therapy. During convalescence, which should extend over months instead of weeks, there should be absolutely no mental strain, physical exertion or stimulation of any kind. It was very difficult for patients as well as physicians to understand this.

Treatment of Empyema.—Dr. DUNCAN EVE of Nashville said that the treatment was purely surgical and usually the sooner it was applied the better, for delay allowed the pleura to undergo changes and caused adhesions to form, thereby interfering with lung expansion. The ordinary surgical methods for the various stages of empyema consisted in aspiration, incision, rib resection and the operations of Schede, Estlander, and Fowler. Cases of recent empyema, incision and proper drainage, or to better put it, rib resection and drainage, would often accomplish a cure, yet in many such operations the results were very unsatisfactory, for the drainage ceased and the lung function was not restored, or a fistula persisted, or even amyloid disease might arise. In many respects a chronic closed empyema was drained, as already suggested, like the recent variety. If, however, after a year's time or such a matter the lung did not fully expand, but instead remained stationary, the Schede or Estlander operation should be made. Tuffier and Depage had both shown, and hundreds of others had confirmed the observation, that if the cavity was sterile it would remain closed and the lung would expand. This, then, must be our practice in civil life in the treatment of empyema, and when one remembered the prolonged suppuration in these cases and the difficulty of obliterating the cavities by various plastic operations, one must admit that here again we were indebted to military surgery for a great advance.

The Cautery in Acute Epididymitis.—Dr. J. C. VINSON of Tampa, Florida, said that the procedure, when properly carried out, was painless. The treatment was essentially an office procedure. The effect upon the infection was obvious. The immediate and remote effects were as good, if not better, than the cutting operation.

The Value of Large Single Doses of Digitalis in the Treatment of Heart Disease.—Dr. G. CANBY ROBINSON of St. Louis stated that the administration of the tincture of digitalis in large single doses was advocated as a useful method of treatment in certain cases of heart disease provided the tincture was standardized, the dosage regulated as described in the paper and the patient was kept under close observation. This method of administration not only brought the heart rapidly under the influence of the drug, but also afforded a much closer means of studying its effect than the older method of small repeated doses. The use of large single doses was apparently not dangerous under the conditions specified. Problems of dosage, especially to body weight, still needed solution. The beneficial effect of digitalis in cases with cardiac irregularity caused by auricular fibrillation was especially emphasized by his experience with large single doses in this condition.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held November 7, 1919.

DR. SETH M. MILLIKEN IN THE CHAIR.

Dislocation of the Carpal Semilunar.—Dr. CHARLES E. FARR presented two patients, demonstrating results following attempted but unsuccessful closed reduction of dislocation of the carpal semilunar. He stated that dislocation of the carpal semilunar was the third most common injury o fthe wrist. The most common injury to the wrist was Colles's fracture; the second most frequent was fracture of the scaphoid, and then dislocation of the semilunar. If one could treat the injury during the first few hours, or even during the first forty-eight hours, good results could be obtained. He presented these two cases together because the injuries were all about alike, occurring in young adults who had fallen and received a trauma like that producing Colles's fracture. The first young man had been splinted for three weeks, and then at the end of six weeks showed a great deal of atrophy. The semilunar was removed and under massage and baking he had made good progress. The second man was hurt in July, and did not come under the speaker's observation until two weeks after sustaining the injury. He had tried to do a closed reduction under the fluoroscope, but the *x*-ray showed that this was not successful. The patient was rather loath to have an open operation, so he was trying to see what could be done for him by massage and baking. In cases not operated on, after three to six months it was possible to get a useful hand, with a limited extension and fairly good flexion. In some cases the range of motion was quite good. The only case in which he had a bad result was one that he did not handle until after the dislocation had been reduced and splinted for eight or ten weeks. In this case there was a luetic complication, atrophy, and a nerve lesion.

In the case shown he had not removed the carpal semilunar bone. The *x*-ray print and plate of this case were shown. In this case attempts at reduction were unsuccessful because of the position of the bone. Dr. Farr said he had also brought with him a plate from the New York Hospital collection, showing a carpal semilunar dislocation with a greater degree of dislocation than any he had ever seen, just to illustrate what was possible in the way of a semilunar disloca-

tion. The lesson he drew from a comparatively small number of these dislocations was that the results were very poor unless the cases were treated early, that early treatment was efficacious and late treatment was not.

Subcutaneous Rupture of the Spleen and Left Kidney.—Dr. Farr presented this case, also. He stated that the patient was a truckman, 32 years of age, admitted to the New York Hospital, July 17, 1919, complaining of pain in the left lumbar region and lower abdomen and hematuria. He gave a history of having been kicked in the left lumbar region three days before by a horse. Immediately thereafter he had pain in the left lumbar region and the left lower chest. The left lower chest was strapped that day by an ambulance surgeon, and the patient returned home. During the next three days he had severe pain in the left lumbar region, some abdominal distention, and hematuria, in which condition he was brought into the hospital. His family and personal history were negative. His temperature at the time of admission was 102.6° Fahr.; pulse, 120, and respirations, 24. He was acutely ill, and quite evidently in pain. The pupils were dilated, regular, but reacted sluggishly. There was no evidence of fractured ribs. The pulse was rapid and of low tension. There was considerable distention of the abdomen, with tympany over the central portion, and upward over the epigastrium. There was shifting dullness in the flanks, suggestive of fluid wave. There was considerable tenderness in the lumbar region, and slight rigidity. There was marked tenderness posteriorly over the left costo-vertebral angle. The bladder was not distended. The probable diagnosis was rupture of the left kidney, with peritonitis. The urinalysis showed the specific gravity to be 1.015, trace of albumen, no sugar, and numerous red blood corpuscles. At operation an incision 8 inches long was made at the outer border of the left rectus, and the muscle retracted inward. The peritoneum was found to contain clean, bloody fluid. A huge retroperitoneal hematoma was found in the region of the left kidney. At this time the patient was in severe shock, and a second transverse incision was made in the middle of the previous incision, and carried outward to the border of the quadratus lumborum. The bleeding was very severe. The left kidney was pulpified, and with practically no pedicle. It could not be delivered, but double clamps were placed upon the vessels *in situ*, and the kidney torn and cut away. The pedicle was ligated with chromic catgut. Free bleeding still persisted. The spleen was then exposed, and found to be torn in two places through the capsule, and bleeding freely. The spleen was removed by clamp and the pedicle ligated with heavy catgut. A Miculicz tampon and rubber drain tube were placed in the transverse portion of the incision. The remainder of the wound was closed in layers, using chromic catgut and silkworm in the skin. The pathologist's report stated that we were dealing with a ruptured spleen and kidney, and that no microscopical report was necessary. Following the operation the patient was in considerable shock. The blood examination showed red blood corpuscles, 2,944,000; hemaglobin, 62 per cent.; white blood corpuscles, 22,000; polynuclears, 84 per cent.; lymphocytes, 16 per cent. Five hundred cubic centimeters of blood was transfused from the brother by syringe method. The transfusion was carried through successfully, and on August 3 the red blood cells had risen to 3,500,000; hemaglobin to 74 per cent.; the white blood corpuscles numbered 14,000; polymorphonuclears, 70 per cent., and lymphocytes, 30 per cent. The urine was negative until August 12, when it showed a trace of albumin, a few red blood cells, and occasional pus clumps. The patient was discharged on August 18, 1919, and had made a slow, constant, and uncomplicated recovery. The wound had healed except for a shallow, granulating sinus at the site of the drain.

Dr. Reginald H. Sayre said he had had some experience with semilunar dislocations, and recalled particularly seeing one case with Dr. B. Farquhar Curtis years ago, which was interesting because the dislocation occurred two months before it came under their observation. They thought it improbable that it could be reduced without open operation. He had the good fortune, in manipulating it, to push the semilunar back into place with his thumb. The man was much concerned for fear it might interfere with his playing golf, but happily he played golf as well as ever. He thought Dr. Curtis had published the *x*-ray plate of this case in his work on surgery.

Dr. Fenton B. Turck said he was interested in the biological side of this interesting case of rupture of the spleen and left kidney. No mention was made of the fact that shock was due to the presence of the macerated kidney tissue. It was well known that as soon as there was destruction of tissue autolysis occurred, resulting in the formation of toxins which had an effect on the splanchnic circulation, leading to the production of all the symptoms of shock. Just as soon as the macerated tissue was removed the shock disappeared. This was in line with the principle enunciated in the treatment of war wounds, namely, that to prevent or overcome shock and avoid infection they must practice débridement. In the early part of the war, before this practice became general, they were losing 80 per cent. of their wounded men. Then they began to do a débridement, and to remove all devitalized tissue, and there was a remarkable decrease in the loss of lives from shock. As soon as devitalized tissue was removed in Dr. Farr's case an immediate reaction took place, and this reaction was due to the antibodies in the blood against autolyzed tissue that was present in the abdomen. It was probable that the removal of the spleen with its autolyzing tissue was an important factor in saving the life of this patient. He merely called attention to this point because this case served so well to illustrate the part played by devitalized autolyzing tissue in the producing of shock and the way in which the antibodies responded when the devitalized tissue was removed, in counteracting shock. Dr. Farr had treated this case in accordance with the methods of the war whereby it was found necessary to remove devitalized tissue in order to save the lives of the patients.

Dr. Seth M. Milliken said he was interested in the statement that the spleen bled three days after the injury. In the cases he had seen the bleeding had pretty well stopped at so late a period.

Dr. W. T. Moynan asked Dr. Farr if he had considered using the cautery to stop the bleeding of the spleen.

Dr. Leon T. Le Wald said he was particularly interested in the case in which the carpal semilunar was not reduced. He wondered whether if possibly it had been mistaken for a partial or complete subluxation, or dislocation of the first on the second row of metacarpal bones, particularly as Dr. Farr had spoken of a partial rotation of the semilunar. Dr. Derby and he had had a similar case, in which they came to the conclusion that they had a dislocation of one row of metacarpals on the other and no dislocation of the semilunar at all. An open operation was performed and this was found to be the case. In an ordinary dislocation of the semilunar the relationship to the radius was entirely lost, but when there was a dislocation of one row of metacarpals on the other the relationship between the semilunar and radius was intact.

Dr. Maximilian Stern said that there were two points in Dr. Stark's case to which attention might be called: One was the possibility of reflex inhibition of function in the better kidney, and the other, the element of hiccough. He stated that he had often observed the inadequacy of the phenol sulphon phthalein test as evidenced by its low output on the better side, both in bilateral and unilateral troubles. In cases in which the blood chemistry had justified surgery, either on the diseased side of a unilateral affair, or on the worse side in bilateral lesions, it was astonishing with what rapidity the better kidney took on normal function. The interesting question, in his estimation, was to what degree a margin for reflex inhibition could be allowed, as he considered it a certainty that the phthalein test in these cases could not be regarded as a guide, and without blood chemistry estimations there would be no justification for operative interference. In reference to the hiccough, he was interested in the fact that its supposed etiology being that of acidosis could have been better treated with bicarbonate of soda solutions per orum, or by proctoclyses rather than by the sedative means preferred by Dr. Stark.

Dr. FARR, in closing, said he had no doubt but that removing the packs that had been introduced during the operation causes a renewal of the bleeding from the spleen. In most of the cases coming under his observation the bleeding had stopped in twenty-four hours or less. Suturing would probably have stopped the bleeding, but it was difficult to get in to suture, and if it was difficult to suture one could not get in with the cautery. Furthermore, he would hesitate to try the cautery on the spleen.

Bilateral Nephrolithiasis.—Dr. MEYER M. STARK presented this patient, a man 36 years of age, whose previous family and personal history were negative. He had several brothers and one sister who were well. There was no tuberculosis, though the facies and habit would indicate this. Nine years ago he began to have symptoms referable to the bladder, frequency in urination, pain, cloudy urine, burning, and tenesmus. There was occasional hematuria, especially after severe efforts. He was cystoscoped last year and treated for cystitis, which was thought to be probably tuberculous. His general health was not much impaired in all these years. Last June he began to have pain in the loin and lumbar region, and about June 30 began to pass stones per urethra. In 22 days he passed 30 stones, one day nine and once two at a time. A casual specimen of urine at this time was shown to be loaded with pus and bacteria. The patient came under the speaker's observation July 22, at which time he complained of dull pain in the left lumbar region, soreness in the penis, frequency and tenesmus. Believing that we had a unilateral lesion and that nephrectomy might be the operation of choice they proceeded to make a complete survey of both kidneys and especially to investigate the right kidney function. Cystoscopic examination on July 24 showed the left kidney not secreting; the right kidney gave off a cloudy urine, pus and bacteria. This was the first intimation of any kind that the right kidney might be affected. Phthalein from the right kidney showed itself in about 12 minutes, about 5 per cent. being recovered in the first half hour. The *x*-ray showed five stones in the left kidney; the ureter and bladder were negative. There was a mysterious shadow on the right side which after investigation they decided was a calculus, although a huge mass was found anteriorly on abdominal examination. The problem with which they were confronted was that of a bilateral lithiasis, one side blocked and the other the seat of a solitary stone. The question here, as in all cases of bilateral nephrolithiasis, was which side to operate first. On July 28 the patient began to have pain in the right lumbar region for the first time with diminished secretion of urine, so that by the morning of the following day it was evident that he was developing an anuria. He secreted only two ounces in thirty-six hours. On account of the acuteness of the complication it was decided to operate on the right side first as an emergency measure. The patient was accordingly operated upon on July 29, and on July 30 passed 60 ounces per urethra. On August 1 he again developed auria, passing only two ounces of urine containing blood and pus. The wound was then laid wide open and the secretion started up again, part of it coming through the dressings and part by way of the bladder; the patient was magically improved by this procedure. In view of the possibility of a recurrence of the anuria, it was decided to operate on the left kidney forthwith, to give the patient every chance to secrete from both kidneys, and on August 2 a rapid nephrotomy was performed. Only four stones were removed, one of which was blocking the ureter. Urine then began to appear in the bladder in good quantities until August 5, when there was no secretion from the left kidney for about eight hours. There was much pain in the region of the left kidney. To further complicate the convalescence the patient then had an attack of hiccoughing lasting forty-eight hours. On August 30 the patient could not urinate standing up and the *x*-ray showed two stones at the neck of the bladder. The patient refused operation. On September 2 he passed one of these stones and on October 3 he passed the other. The wounds healed and he was discharged October 15. At that time the urine was slightly cloudy, and contained some pus but no bacteria. The patient was gaining steadily in weight. He had weighed over two hundred pounds; in July he went down to 140, and he now weighed 160 pounds.

Dr. EDWIN BEER said that bilateral nephrolithiasis was unfortunately a rather common condition. He had four patients with this condition at the present time in the hospital. It was important to realize the frequency of bilateral nephrolithiasis inasmuch as surgeons were altogether too hasty in removing kidneys. It was important to preserve as much kidney parenchyma as possible. Cases had come under his observation in which one kidney had been removed and within a few years it would be found that the other kidney was a stone bearing kidney. These large stones were liable to recur and there was no method available to prevent their recurrence. He had one patient who had been operated on by another surgeon and a stone bearing kidney removed. Within two years the previously second healthy kidney developed a stone with pyelonephritis and anuria. Nephrotomy, recapsulation and prolonged drainage were carried out. Stones recurred and had to be removed by four further nephrotomies, one each year during the past four years. He would like to have the patients they had seen this evening brought back in a year. It made no difference whether the kidney was washed through the nephrotomy wound, whether they gave mineral water or tap water, or whether they irrigated through a ureter catheter, stones were liable to continue to form in these cases of large stones which deformed the pelvis. Hiccough was very common in suburemia, and was liable to occur after anesthesia; even gas-oxygen anesthesia diminished kidney function and was likely to cause a deeper suburemia. He had seen this condition last ten days. Another interesting point was which side to operate upon. Dr. Stark did widely to operate on the side with the pain, because the side with the pain was likely to have the better organ, and the one which had been secreting last. His result was very excellent, but he would like to see the case again in a year, and find how many new stones had developed.

Dr. W. T. MOYNAN said he had had the opportunity of seeing a number of these cases. In Paris they had been using a proprietary remedy called urodonal for the past four years which they claimed prevented the recurrence of stones.

Dr. FARR said they were advertising that remedy in every paper in Paris and he did not think this society would have much use for it.

Dr. MEYER M. STARK, in closing, said he did not think the reflex inhibition was playing a great part in this case. He thought the lack of secretion was due to mechanical conditions as the pelvis of the kidney fitted tightly over the calculus, and it was secreting prior to the acute condition. After the first operation there might have been some reflex inhibition. Dr. Beer had sounded the keynote when he said that we should examine both urinary tracts so that we might be sure of what we were dealing with. At the time of the examination an *x*-ray should be taken with the catheter in the ureter, and it was advisable to make a thorough examination at one sitting. There was no doubt but that recurrence did happen quite frequently and no one knew how to prevent it. One might drain the pelvis of the kidney through the lumbar wound instead of into the bladder.

Dr. BEER said that would not prevent recurrence.

Dr. STARK said he agreed that it would not prevent recurrence but it would help at first during the period when the patient might develop anuria after the anesthesia. The patient was given ether first and then gas and oxygen second. He developed hiccoughs and acidosis and was treated with every remedy without avail. Finally a visitor came in and picked up a candied cherry and gave it to the patient and the reflex from sucking on the cherry stopped the hiccough.

Paraffin Gravity Drainage, the Only Rational Surgical Drainage.—Dr. A. L. SORESI made this presentation in which he said the necessity of evacuating pus was admitted by all surgeons, what was not fully appreciated was that the means actually employed did not drain as they should and that too often they were the direct or concomitant cause of many complications. Another important point about drainage was that instead of draining any liquid from organs and tissues

where it should not be, it was much better to prevent its formation and accumulation and this could be easily done in practically all cases. By this prevention he meant the prevention of the accumulation of any liquid in a clean or infected wound, as for instance after a laparotomy; where at times there formed in the wound an accumulation of liquid that might also become infected. We thought it was good surgery if such an accumulation of liquid was perfectly drained, but it was better surgery if we applied to the wound a means that would prevent in practically all cases of clean and infected wounds the formation of such accumulation of liquid. The accumulation of liquid caused delay of union by preventing the immediate contact of tissues and favoring the absorption of products that were dangerous to the organism. Therefore the surgeon has not only to employ a means that really drained, but a means that also prevented the formation of collections of liquids where they should not collect, (1) Such means must really and effectively drain out the pus or any other liquid as rapidly as it formed, preventing absolutely any accumulation of the same. (2) It must not be the immediate or concomitant cause of any trouble or complication either local or general, either at the moment it was applied or at any time afterwards. (3) It must never in any manner retard the complete healing of the tissues drained, but on the contrary must be a help to the rapid and complete healing of the tissues. Before discussing this method of drainage, some very important physical and physiological facts would have to be considered. It was known that all means employed at the present to obtain surgical drainage relied on the fact that liquid would run through small or large tubes, by small tubes he meant the tubules, as found in the gauze when it was used as capillary drainage, and that pus, blood, or any other organic secretion adhered to the means employed as drainage, and so blocked it; in many cases the means intended to drain, had actually acted as a tampon. The reason of this occurrence was that organic liquids were not mere liquids, they were really a suspension of corpuscles and had a tendency to adhere to the bodies with which they came in contact; so that nature in order to keep certain liquids fluid and circulating had lined the special organs in which these liquids were contained with special cells to which the liquids did not adhere, so if we wanted really to drain we had to imitate nature and line our means of drainage with substances to which the organic liquids would not adhere. This substance was paraffine to which nothing adhered, neither blood, pus, urine, nor tissues, either normal or inflamed. The physical principle to be taken into consideration in dealing with surgical drainage was the manner in which liquids moved from one container to another; liquids move only in accordance with the law of gravity or capillarity, or when under pressure, as it happened with the water that came out of the faucets. Applying these laws to surgical drainage, we saw that drainage was only possible under two conditions; either we placed the drainage in such a manner that the liquid was carried out by gravity, or we had to wait until there was a certain pressure that would push the liquid out of the cavity, because drainage by capillarity could not be applied to any of the liquids found in the body. If we drained according to the law of gravity, the liquid would come out of the wound as soon as it was formed, that was, provided the means employed to drain did not hamper drainage; if, however, we did not drain according to the law of gravity, we had to rely on the pressure that the walls of the wound exercised on the liquid contained in them to push it out of the wound; this meant that there must necessarily be a certain amount of liquid in the wound, inflammation of the tissues, possibility of absorption, and that only the excess of the liquid found in the wound would come out through the drainage, so there would always be in the wound a certain amount of liquid which would delay union and complete healing. Hence the only rational drainage was one that acted by gravity and any means employed to carry off the drainage must be a substance to which nothing adhered. Nothing adhered to paraffin and any commercial paraffin was suitable for drainage. Paraffin was melted in a double boiler, or better in two enameled trays, as used in photography, one larger containing the water and a smaller one containing the paraffin, and was used directly by pouring the melted paraffin into the wound, this constitutes the block paraffin drainage, or gauze in strips of different widths and shapes, as T, Y, or fan-like, threads of cotton, wicks, etc., were dipped in the melted paraffin, so that after the paraffin solidified they were completely covered with paraffin. Paraffinated gauze, thread, etc., could be prepared in advance and be had ready for use by keeping them in any antiseptic or aseptic liquid, such as alcohol, plain or slightly iodized. Paraffin drainage was specially recommended in abdominal cases, because although drainage could not be obtained for a long period on account of formation of adhesions, paraffinated gauze did not cause *per se* the formation of adhesions and therefore is better than any other means. The drainage of the pleura was obtained by means of special paraffinated instruments. At times paraffinated gauze was used as a lining to a cavity and was filled with cotton or gauze. In addition to the objections already cited, common drains caused pain while they are applied; they must be changed often, thus causing repeated pain, reinfection, and traumatism to the tissues; while on the other hand, paraffin drainage did not cause any pain while it was being applied and did not need to be changed because it lasted practically forever; it was applied without the help of any instrument, it adapted itself to the cavity to be drained, had none of the drawbacks of other drainages. Tubes, gauze, etc., irriated the tissues, kept in moisture and were soaked with infectious material, so favoring multiplication of microorganisms. They could cause serious damages to nerves, blood vessels, etc., and when changed caused trauma, hemorrhage, and pain. Paraffin drainage did not cause any of these troubles and helped the healing of tissues by draining out any liquid as it forms. Paraffin gravity drainage helped healing by first intention of clean or slightly infected wounds; the wound must always be closed and the drainage brought out by stabbing the tissues at the lowest portion of the wound; infected wounds could also be closed, provided the dead spaces were obliterated by means of the author's elastic closure and paraffin gravity drainage was applied, as in clean wounds, after dead tissues and foreign bodies had been removed.

Automatic Gravity Anesthetizer.—Dr. A. L. Soresi presented a simple contrivance by which the supply of ether given during anesthesia could be regulated without the constant attention of an attendant.

Dr. Edward Wallace Lee said the presentation had been very interesting and striking, only perhaps if Dr. Soresi had carried his paper further he might have mentioned some other things. It was well known that the healing of wounds was not dependent upon drainage by gravity or the removal of pus or débres. Some wounds could be drained indefinitely and yet they would not heal simply because they were infected. Drainage by gravity or in any other way did not bring about healing unless that wound became sterile. One must sterilize a wound before he could expect it to heal. If one depended upon gravity for drainage it would often take a very long time because there were many difficulties to be overcome unless one got the stab wound exactly at the bottom of the pit of the wound. Why not employ, not a cigarette drain, but a gauze drain protected by rubber tissue as rubber tissue was smooth and non-adherent. Granulations would not accumulate around it, it was easily introduced and easily withdrawn. Why was rubber tissue not as convenient as paraffin? Another objection to paraffin was that at a temperature of 98° or 100° F. was that it was liable to flake off and little flakes would be left in the wound, and they were not always as innocuous as it might appear, for they would act as a foreign body. This was a great deal like the way in which Bipp was used. We heard so many reports in which it was stated that it was a great success and then other reports stated just the contrary so that it was hard to tell what its value was. Furthermore, with reference to the apparatus for regulating the supply of ether, he did not think that was practical in obstetrical cases because the patient did not hold still and it would require some one to hold her head so that she would receive the ether.

Dr. Soresi said that he had just mentioned the pos-

sibility of using this device for regulating the amount of ether in case of labor in a casual way. He was not an obstetrician, but it would be quite possible to get an assistant who could hold the patient's head in position when one could not get someone to administer an anesthetic. With this device the physician would know just how much anesthetic the patient was getting, or he could easily direct an assistant which way to turn the stopcock to regulate the supply without handling the apparatus himself.

Dr. EDWIN BEER said Dr. Soresi had spoken of using paraffinated gauze in the peritoneal cavity. He would like to know whether Dr. Soresi had done any experimental work on animals to see to what extent adhesions formed intraperitoneally around paraffin strips.

Dr. SORESI replied that he had not carried out a systematic experimental work about adhesions forming around paraffinated strips of gauze on account of having been in military service for four years, but that he had observed that adhesions formed around paraffinated gauze as they form around any foreign body that was introduced in the peritoneal cavity. But adhesions were not formed where the paraffinated gauze had been applied, moreover, the removal of paraffinated gauze not causing any bleeding or any trauma, adhesions did not follow its removal, as was the case with plain gauze. Another thing he was using was a vulcanized cement dissolved in ether. He painted the skin with the ether rubber solution and it made a film of rubber over the skin, which made a perfectly sterile surface, and one could dispense with iodine and after painting the skin in this way one could take out any abdominal organ and lay it right on the skin, without risk of infection or irritation. The rubber solution was also excellent to prevent irritation, as, for instance, after a suprapubic prostatectomy it would protect the skin from the irritation caused by the urine. He was in the habit of putting a little dye in the solution, so that he could be sure that the entire operative field had been covered. The solution was made by using one part of rubber to about four or five of ether. Any kind of automobile rubber cement answered the purpose. Dr. Soresi stated that it was not possible to solve all the problems of surgery by continuous drainage. One must first do good surgery; all devitalized tissue must be removed and one must remember in attempting to get sterilization that what killed microbes also killed cells. Then, too, a great deal depended upon the resistance of the patient. We had wonderful results in the war, because we were dealing with the flower of young manhood in prime condition. He did not believe that everything that gave good results during the war among the soldiers would give equally good results among the civilian population, where the physician has to treat many people with lowered resistance.

Fracture Reducer of Heitz-Boyer.—Dr. KENNETH BULKLEY demonstrated this apparatus, the description of which was published in *Le Bulletin de Methodes de Chirurgie*, October, 1918.

Dr. JOHN C. A. GERSTER said he found this instrument simpler and easier to manage than others of its kind and described some of its advantages.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Miscellany.

Passing of a Madrid Landmark.—Muñoz in *El Siglo Medico* for August 2, notices the passing of the ancient "Cafe Suizo" to make way for a bank building. This famous resort contained among other institutions a special table for medical men. It enjoyed the patronage of most of the celebrities—artists, literati, politicians, and men of affairs. Here celebrated practitioners of medicine were wont to gather at the close of morning office hours, from 12 to 1. Presently a dozen would be seated about the marble board. The medical men debated everything but medicine; the arts, sciences, literature, life in Madrid, and elsewhere. Topics like politics and religion, however, were eschewed in the interests of courtesy. Evidently a consensus of opinion was often the outcome of a debate, for the opinion of the "Swiss table" on a given subject seemed to carry weight in outside circles. A list is given of the distinguished medical men who have gathered at the board and among foreigners who have been luncheon guests there are mentioned Brouardel of Paris, Moure of Bordeaux, and Sanarelli of Rome. Cortezo, for many years head of the "Swiss table," will induct his brethren of the medical profession into another celebrated resort.

Steam as a Bedbug Eradicator.—The use of live steam to eradicate bedbugs has been practised very successfully by the Booth-Kelly Lumber Co. of Eugene, Oreg., an account of which has been furnished the United States Public Health Service by Dr. T. Tharaldsen, of Portland. (*Public Health Reports*, November 28, 1919.) The bunkhouse is a T-shaped building of 70 rooms, each 10 by 12 feet, and has an 8-foot hallway running the full length of each wing. It is of ordinary frame construction. The heating system consists of radiators in the halls and four 1½-inch pipes running the full length of the building and exposed in each room. In heating the building the pressure in the steam pipes is reduced by means of a reducing valve to 10 to 12 pounds to the square inch; but in steaming to superheat the building to kill the bedbugs the reducing valve is opened and the pressure is increased to 80 or 100 pounds. The windows and doors are shut, but no attempt is made to calk any of the cracks. Articles which might be injured by steam are removed, but all bedding, mattresses, and clothing are left in the rooms. The plugs in each room are opened and the valves on the radiators in the halls are turned on. It requires about two hours to raise the temperature of the building to 160° F. This temperature is then held for approximately three hours. After the steaming, a great many of the dead bugs are found on the floors.

In the first trial made it was found that a temperature of about 150° F. killed all the bugs in sight, but in this trial only one room at a time was steamed and this method failed to get the bugs between the walls and those deeply imbedded in the mattresses. The method of steaming all of the rooms at the same time proved more effective. The company states that two months after the steaming no signs of bedbugs had been found, and that it is the intention to steam the bunkhouse three or four times a year.

INDEX.

A

Abdomen, acute, treatment of the, 1067; gunshot wounds of the, the treatment of, 392.

Abdominal injuries, 176; organs, further experiences with roentgen examination of, following oxygen inflation of the peritoneal cavity (pneumoperitoneum), with lantern slide demonstration, 946.

Abortion, legalized, 118.

Abscess, hepatic, the rôle of the portal vein in the genesis of, 112; lung, in children, 38; of rectus muscle following influenza, 351; of the liver, 863; of the spleen, tropical idiopathic, 700; perinephritic, a new *x*-ray sign of, 527.

Accident, cause of, injury or disease?, 422; policy, violation of law voiding, 929.

Acidosis, in children, 306; in pregnancy, 307; of epidemic influenza, alkali treatment applied to the, 306; on, 985.

Acne, oil, 491.

Acromegaly, functional diagnosis of the pluriglandular syndrome in, 525.

Adenoids, chronic conjunctivitis, and photophobia—a case and cure, 255; semicentennial of the discovery by Meyer of, 222.

Adenoma mammary cancer, significance of, 863.

Adenomyoma, two early cases of, 862.

Adrenal insufficiency, clinical forms and treatment of, 814.

Aged, amours of the, and their cost, 806.

Agglutinins, produced by Pfeiffer's baccillus, an experimental research into the specificity of the, 1027.

Air, the pollution of the, 117.

Air-pressure, differential, the necessity for the application of, in thoracic operations, 617.

Albuminurophobia, 599.

Alcohol, delayed reaction to, expressed as fear states, 201; in its social compensatory aspects, 821.

Alcohol-syphilis association, the, 599.

Alcoholic drinks, government regulates dispensing of, by physicians and druggists, 70.

Alcoholism and personality, 819; some psychological aspects of, 820; two unusual cases of, 58.

Alienation among the primitive Peruvians, 160.

Alimentation during the war, the physiology of, 168; the physiology of: results obtained during the war, 123.

Alkaptonuria, 550.

Alternation of generations and its bearing upon cancer, 476.

Alvarenga prize, the, 511.

Ambulance, aerial, planned for army, 27; Corps, American, demobilized, 206.

Amputation, early, the necessity for, 430; stumps, abstract of the Harveian lecture on nerves in, 33; the no-flap or guillotine: an unfortunate resurrection, 302.

Analgesia, postoperative, 866.

Anders, J. M.: Treatment of influenza and its pulmonary complications, 223.

Anemia, anaplastic, the course of the blood changes in a case of, 1027; pernicious, gastrointestinal disturbances in, 340; pernicious, a long remission in, 436; pernicious, transfusion of blood in, report of an interesting case, 436; pernicious, urobilin and urobiligen of stool and urine in, 771.

Anergia and the predisposition to infections, 201.

Anesthesia, local, abdominal surgery under, 390; local, some adjuncts which promote efficiency in the use of, 865; nitrous oxide-oxygen in France, 856; the administration of, in obstetrics, gynecology, and abdominal surgery: safety factors in the teamwork of operator and anesthetist, 864; Trendelenburg ether, in pelvic surgery, 390.

Anesthetics, local, the pharmacology of the, 770.

Anesthetizer, automatic gravity, 1072.

Aneurysms, 1068.

Angina pectoris, 575.

Animal experiments with bacteria isolated from influenza and pneumonia, 524.

Antenatal care, the results to be expected from, 298.

Anthrax, protection against, 383.

Anti-drug law fails up-state, 246.

Antimony, death from overdose of, 574.

Antinarcotic law, the, 741.

Antituberculosis federation proposed, 932; work, 31.

Antityphus army starts for Poland, 160; campaign in Siberia, 933.

Aortic disease in soldiers, observations on, 676; intima, sudden detachment of (so-called dissecting aneurysm), 515.

Aphonia, functional, 75.

Aphorisms, human nature in, 574.

Appendicitis, chronic, Rovsing's sign in, 508; etiology of, 1063; the etiology of, 36.

Appendix, radiography of, 508.

Archibald, Edward: a general consideration of wounds of the head in the war, 16.

Archivos de Biologica de Sao Paulo, 296.

Army hospitals, two, close, 600; United States, efficiency and sanitation in the feeding of the, 746.

Arrhythmia, significance of, in the infections of childhood, 735.

Arsphenamine administration, further evidence in support of the concentrated method of, 28; in pneumonia with delayed resolution in syphilitic soldiers, 812.

Arterial tension, low, 1026.

Arteritis, influenza, the pathogenesis of, 332.

Artery, deep epigastric, rupture of the, as a clinical entity, with the analysis of a case, 714.

Arthritides, infectious, with especial reference to foci of infection, 564.

Arthritis, chronic, in the army: observations based on a survey of four hundred cases, 80; chronic, studies on, in the army, 1034.

Ascaris lumbricoides, migrations of the, 765.

Aspidosperma, the therapeutics of, 698.

Asthenia, neurocirculatory (soldiers'), irritable heart, the explanation and treatment of the effort syndrome, 144.

Asthma, bronchial, the results of nonspecific vegetable protein therapy in cases of, 725; hayfever and, 494.

Astragalectomy, experiences with, 561.

Ataxia, the Maloney method in the treatment of, 268.

Athletic field for the University of Paris, 464.

Atrophy, gastric cell primary, 339.

Auditory canal, external, furunculosis of, 543.

Auscultation, centenary of, 748.

Autopsy service, the, of the American Expeditionary Force, 527.

Aviator, military, the psychology and pathology of the, 123.

Ayerza's disease, 524.

Azotemia, a mild, meningeal reaction and albuminuric retinitis in the course of, 895.

B

Babcock, W. Wayne, and Spear, Irving J.; questions in relation to the treatment of peripheral nerve injuries, 664.

Babies, better, for France, 222; few sick, in New York, 471; Italian, perishing for lack of milk, 234; overfed, 737; saving Belgian, 205.

Back, disability following injuries to, in industrial accidents, 565.

Bacteriological chair, founding of, in London, 73; note, 626.

Bacteriology, the, of the blood, 817.

Bamberger-Marie disease, see *Osteoarthropathy.*

Bands in the right upper abdominal quadrant, a study of certain, illustrated by cases, 862.
Barnes, G. E.: the explanation and treatment of the effort syndrome, neurocirculatory asthenia, (soldiers') irritable heart, 144.
Barnes, Noble P.: the general treatment of influenza, 686, 710.
Bastian, Charlton, the life work of, 30.
Bateson, J. C.: the influenza scare, 336.
Benedict, A. L.: donor and receptor in regard to blood groups, 761.
Benzyl benzoate, 1061.
Beriberi, mistaken diagnosis of, 119.
Bilious fever, hemoglobinuric, of tropical countries, 729.
Biology, general; a subject to be taught in medical instruction, 123.
Birth control case dismissed, 807; rate, British, shows gains, 1057; registration, the new, 161; statistics, Swiss, 979.
Blackwell, H. B.: Furunculosis of the external auditory canal, 543.
Bladder, female, the hairpin as a foreign body in the, 610; tumor of, in women, their diagnosis and treatment, 712; function, a study of, 711.
Blind, Britain takes steps to care for, 510; society to aid, incorporated, 767; the, of Mexico, 359; welfare of the, 513.
Blood, chemical changes in the, in disease, their significance and value in diagnosis and prognosis, 816; chemical examination of the, in children, 41; chemistry, 290; groups, donor and receptor in regard to 761; serum, the physical state of the, in relation to its agglutinin and antibody content: the effect of friction and pressure, 121; sugar and diabetes, 1029; transfusion, see *Transfusion*.
Bloomfield, M. D.: Report of a case of acute gangrenous pancreatitis, 322.
Blue, Rupert: correction of erroneous statements in the *Chicago Daily Tribune*, 673.
Board of Health's power to close schools during emergencies, 728.
Body-weight, diurnal variation in, in tuberculous patients, 813.
Boehme, G. F., Jr.: Fatal case of aspiration pneumonia caused by the ingestion of zinc stearate, 364.
Bolsheviki attack hospital train, 26.
Bone graft, self-retaining slide, 779; graft, the Delagenière, 776; grafting, early, in wounds, 121; grafting operations in the treatment of ununited fractures of the mandible, results of, 167.

Book Reviews:

A proposito del tratamiento de la epilepsia, by Miguel Arango, 254.
Advanced suggestion (neuroinduction), by Haydn Brown, 170.
Alcohol, the whole truth about, by G. E. Flint, with an introduction by Abraham Jacobi, 79.
Ambulance de l'Océan (La Panne), Vol. ii, No. 1, published under the direction of A. Depage, 79.
American Surgical Association, transactions of the, Vol. xxxvi, edited by John F. Binnie, 773.
Anatomical diagrams for the use of art students, by James M. Dunlop, 738.
Autobiography of an androgyne, by Earl Lind ("Ralph Werther"—"Jennie June"), edited, with introduction, by Alfred W. Herzog, 37.
Aviation, the medical and surgical aspects of, by H. Graeme Anderson, with chapters by Martin Flack and Oliver H. Gotch, and an introduction by Lord Weir of Eastwood, P. C., 709.
Bacteriology and protozoology, elementary for the use of nurses, by Herbert Fox, 79.
Bidrag til den medikamentelle Fodselshjaelp. Klinisk Forsok Med Kinin, Hypophysin og Pityitrin, by Georg Benestad, 254.
Blind, the, their condition and the work being done for them in the United States, by Harry Best, 170.
Cerebrospinal fluid in health and disease, by Abraham Levinson, 709.
Cheerio! by Harold M. Hays, 389.
Chemistry for nurses, a text-book of, by Fredus N. Peters, 709.
Chronic intestinal stasis, the operative treatment of, by Sir W. Arbuthnot Lane, 170.
Clinical case-taking, an introduction to elementary clinical medicine, by Robert D. Keith, 300.
Colloids in biology and medicine, by H. Bechhold, authorized translations from the second German edition, with notes and emendations by J. G. M. Bullowa, 254.
Consumption, the science and art of deep breathing as a prophylactic and therapeutic agent in, by Shozaburo Otabe, 389.
Diet in health and disease, fifth edition, by Julius Friedenwald and John Ruhräh, 211.
Disease prevention, today's problem in, by John H. Stokes, 896.
Dyscytogenese hypocytopoietique dysentrophique, ou cancer, by Docteur Naame, 815.
Ear, diseases of the, in school children, an essay on the prevention of deafness, by James Kerr Love, 773.
Français enseigné par la méthode intuitive et directe, by P. Dessagnes, 389.
George Williams Hooper Foundation for medical research, collected reprints from the, Vol. iii, 1917-1918, 211.
Geriatrics, by Malford W. Thewlis, 738.
Gynoplastic technology, with a chapter on "Sacral anesthesia," by Arnold Sturmdorf, 815.
Health officer, the, by Frank Overton and Willard J. Denno, 709.
Heart, the nervous. Its nature, causation, prognosis, and treatment, by R. M. Wilson and John H. Carroll, 857.
Hookworm disease, the control of, by the Institute method, Publication No. 8, the Rockefeller Foundation, International Health Board, by H. H. Howard, 211.
Hughes's nerves of the human body, with plates, revised by Chas. R. Whittaker, 37.
Hygiene and public health, by George M. Price, 738.
Hygiene for the nursery, by Louis Starr, 37.
Infants and children, diseases of, by Henry Dwight Chapin and Godfrey Roger Pisek, 1019.
Instituto Cruz, resumo historico (1899-1918), by Ezequiel Dias, 857.
Internal secretions, the, and the nervous system, by M. Laignel-Lavastine, translated by F. T. Robeson, 559.
International medical annual. A year-book of treatment, and practitioner's index, by various contributors, 738.
Irish ethno-botany and the evolution of medicine in Ireland, by Michael F. Maloney, 815.
Johns Hopkins Hospital Reports, Vol. XVIII, 559.
Lenzmann's Manual of Emergencies, medical, surgical and obstetric, by J. Snowman, 79.
Lettsom, John Coakley, and the foundation of the medical society. Being the presidential address delivered before the Medical Society of London on Oct. 8, 1917, by St. Clair Thomson, 896.
Lotta contro la malaria mediante. La grande e piccola bonifica e la disinfestione idro-aerea antanofelica, by Claudio Fermi, 815.
Manual of laboratory diagnosis, compiled by H. J. Bollinger, 343.
Materia medica for nurses, a text-book of, by A. L. Muirhead, 896.
Mayo Clinic, Rochester, Minn., collected papers of the, Vol. x, 1918, edited by Mrs. M. H. Mellish, 559.
Medical Clinics of North America, Vol. 2, No. 4, January, 1919, Vol. 2, No. 5, March, 1919, 343.
Medical Clinics of North America, Vol. 2, No. 6, May, 1919, 709.
Medical Clinics of North America, the, Chicago number, Vol. 3, No. 1, July, 1919, 815.
Medical Record visiting list or physician's diary for 1920, 857.
Memorias do Instituto Oswaldo Cruz. Tomo X. Faciculo, 1918, 815.
Microbiological Laboratory (Government Bureau of Microbilogy), eighth report of the, for the year 1917. Being Part V of the Report of the Director-General of Public Health, New South Wales, for the year ended 31st December, 1917, 772.
Milk, by Paul G. Heinman, 773.
Nerve control and how to gain it, by H. Addington Bruce, 37.
Nervous systems, the elementary, by G. H. Parker, 1030.
Nursing, industrial, for industrial, public health and pupil nurses, and for employers of labor, by Florence Swift Wright, 857; the higher aspect of, by Gertrude Harding, 857.
Obstetrics, the operations of, embracing the surgical procedure and management of the more serious cases, by Frederick Elmer Leavitt.
Orthopédie instrumentale, by Gabriel Bidou, 1030.
Osteomyelitis, chronic traumatic; its pathology and treatment, by J. Renfrew White, 773.
Oxford medicine, Vol. I, Parts 2 and 3, edited by Henry A. Christian and Sir James Mackenzie, 211.
Pharmacology, experimental, by Hugh McGuigan, 896.
Physical diagnosis, by Richard Cabot, 1030.
Physiology, the new, and other addresses by J. S. Haldane, 343.
Pituitary, the, by Blair Bell, 738.
Plastic Surgery of the face, head and neck, by Joseph C. Beck, 857.
Pneumonia, the pathology of, in the United States Army camps during the winter of 1917-1918, by W. G. MacCallum, 300.
Progressive Medicine, edited by H. A. Hare, assisted by L. F. Appleman, March 1, 1919, 79.
Progressive Medicine, edited by H. A. Hare, assisted by L. F. Appleman, June 1, 1919, 254.
Progressive Medicine, edited by H. A. Hare, assisted by L. F. Appleman, September 1, 1919, 896.
Prothèse fonctionelle des blessés de guerre, by Ducroquet, with preface by Aug. Broca, 37.
Psychiatrist, thoughts of a, on the war and after, by William A. White, 1030.
Psychiatry, the Don Quixote of, by Victor Robinson, 389.
Psychoanalysis, papers on, by Ernest Jones, 37.
Pye's surgical handicraft, edited by W. H. Clayton-Greene, 300.
Rational therapy, by Otto Lerch, 170.
Recherches récentes sur les ictères, by M. Brule, 300.
Reconstruction therapy, by W. R. Dunton, Jr., 300.
Researches on the pathology of mustard gas (dichlorethylsulphide) poisoning. University of Michigan contributions from the pathological laboratory, Vol. ix, 1918-1919, by A. S. Warthin and C. V. Weller, 211.
Rockefeller Institute for medical research, studies from the, Vol. xxx, 211.
Skin, diseases of the, by J. H. Sequeira, 170.
Soldier's heart and the effort syndrome, by Thomas Lewis, 211.
Speech disorders, manual of exercises for the correction of, by May Kirk Scripture and Eugene Jackson, 254.
Stenosi esofagia da diaframmi di shrapnell penetrato nel mediastino posteriore, by Alfonso Poppi, 254.
Surgery, aids to, by Joseph Cunning and Cecil A. Joll, 300.
Surgery, experiences in, with the Second Division of the American Expeditionary Force, by Burton James Lee, 738.
Surgery in war, second edition, by Alfred J. Hull, with preface by Lieut.-Gen. T. H. J. C. Goodwin, 389.
Surgery, Military, of the ear, nose, and throat. Medical War Manual No. 8, by Hanan W. Loeb, 79.
Surgery, orthopedic, a treatise on, sixth edition, by Royal Whitman, 607.
Surgical aspects of typhoid and paratyphoid fevers, by A. E. Webb-Johnson, with foreword by Lieut.-Gen. T. H. Goodwin, 300.

Surgical clinics of Chicago, the, Vol. II, No. 6, December, 1918, 79.
Surgical clinics of Chicago, Vol. III, No. 1, February, 1919, 559.
Surgical clinics of Chicago, Vol. III, No. 2, April, 1919, 559.
Surgical treatment, in three volumes, by James P. Warbasse, 343.
The itinerary of a breakfast, by J. H. Kellogg, 857.
The realities of modern science, by John Mills, 559.
Therapeutics, practical, a text-book of, by Hobart Amory Hare, 37.
Training school methods for institutional nurses, by Charlotte A. Aikens, 738.
Trench fever, a louse-borne disease, by Major W. Byam; Captains J. H. Carroll; J. H. Churchill; Lyn Dimond; J. E. Sorapure; R. M. Wilson and LL. Lloyd, 607.
Trichomonosis, Intestinal, by Edmundo Escomel, 211.
Tuberculosis, pulmonary, by Maurice Fishberg, 518.
Tuberculosis, pulmonary, rules for recovery from, by Lawrason Brown, 518.
Turner, Sir William, K. C. B., F. R. S., Professor of Anatomy and Principal and Vice Chancellor of the University of Edinburgh. A chapter in medical history, by A. Logan Turner, 607.
University of Iowa Studies in Medicine, Vol. I, No. 5, January, 1919, 211.
Venereal diseases, by C. H. Browning and David Watson, 896.
War surgery of the face, a treatise on plastic restoration after facial injury, by John B. Roberts, 559.
War wounds, the early treatment of, by H. M. W. Gray, 518.
Wounds and injuries, the after-treatment of, by R. C. Elmslie, 607.
Boorstein, Samuel W.: obstetric paralysis (Erb's palsy), 790.
Bossi, assassination of, 65.
Boylston Medical prize for 1919, 807.
Brain injuries, 175; volume, therapeutic application of the alteration of, by the intravenous injection of glucose, 647.
Breakfasts, trial, 1029.
Breast, tumors of the, based on a study of seventy-seven cases personally observed, 864.
Bright's disease, the production of, by feeding high protein diets, 525.
Bronchi, dilatation of the, 941.
Brose, L. D.: eye and ear symptoms in basal cranial injuries, 1012.
Bubonic plague in New Orleans, 766.
Bulkley, L. Duncan: Common colds and grippe, 627; posture in defecation, 1053.

C

Calculi, silent renal, 893.
Calomel inunctions, a clinical study on the use of, 853.
Camphorated oil tumors, 812.
Cancer, a new technique on the treatment of, 1042; alternation of generations and its bearing upon, 476; and the war, 113; does the cure of, depend upon oxidation of the tissues? 9; in women; educational cancer campaign among the medical profession and the laity, 863; inoperable, a preliminary note on the treatment of, with selenium, 813; of the face, reconstruction operations in cases of, 305; of the gall-bladder, 47; of the pancreas, 527; of the stomach, 351; of the stomach, anasarcous form of, 477; of the stomach, intravenous injections of pancreatic extract in, 856; of the stomach, surgery of, 517; of the uterus, age distribution and age incidence in 500 cases of, 711; Professor Hartman on, 15; propaganda, 1028; radium treatment of, 765; significance of mammary adenoma, 863; uterine, further observations on the radium treatment of, 712.
Canned goods, army, Health Department supervises sale of, 510.
Canning, home, the dangers of, 1021.
Carbonic acid snow, priority in the use of as a caustic, 68.
Carcinoma of the stomach, surgical treatment of, 782; see also *Cancer*.
Cardia, functional impermeability of the, 478.
Cardiac diagnosis in the light of experiences with army physical examination, 482; hydropsy, dietetic and drug treatment of, 36; lesions, auscultatory percussion in diagnosis of, 581; massage, theories on, as a means of resuscitation, 771.
Cardiospasm, *x*-ray findings with the delineator in, 715.
Cardiovascular disease, some danger signals in, 772; function, some secondary characters of the, 483; phenomena associated with war neurosis, 745; studies of the war, the application of the, to civil practice, 982.
Caries, spinal, rapidly fatal, 604.
Carpenter, the Wesley M., lecture, 897.
Carriers, meningococcus, two studies of, 854.
Casualties, infantry, higher than those of aviation, 26.
Catarrh, chronic nasal, the bacteriology of, and its treatment by autogenous vaccines, 476.
Catharsis and laxatives, the abuse of in infancy and childhood, 41, 275.
Cecum, the value of the "no good"—plication of the, 558.
Cerebral compression, traumatic, pulse pressure in, 779.
Cerebrospinal fever, remarks on its epidemiology, prevention, and clinical features, 340.
Cesarean section, elective, 610; its indications and technique, 860.
Chancre, fifteen hundred cases of, 506.
Chemical industries, national exposition of, 71.
Chest injuries, the treatment of, 88; wounds in war, from the medical standpoint, 479.
Child, a mentally deficient, with a protracted elevation of temperature, 880; health organization, report of, 732; special factors in management favoring normal development of the child, 951; the nervous, and his management, 42; the spasmophilic, 936; welfare, 31; welfare station, mobile, 731; welfare work, see *Welfare work;* work, Belgian doctors volunteer for, 473.
Child, C. G., Jr.: episeotomy: its relation to the proper conduct of the perineal stage of labor, 142.
Childhood, acute infections of, 1067; chorea of, 930; double empyema in, 289; nutrition in, the measure and development of, 261; organotherapy in certain diseases and conditions of, 529; the abuse of catharsis and laxatives in infancy and, 41, 275.
Children, acidosis in, 306; affect disturbances in, 388; Belgian, 117; chemical examination of the blood in, 41; foundation for destitute and abandoned, 202; free dental clinic for, 383; French, natality, morbidity and mortality of, in regions occupied by Teutons, 986; French, welfare work for, 248; lung abscess in, 38; mental retardation among, 25; obstipation in, 260; recent developments in out-patient work, 39; some clinical experiences in the treatment of, with tuberculin, 39; spastic paralysis in, 453; tuberculin therapy in, some practical hints on, 459.
Chiropody, see *Podiatry*.
Cholecystectomy, the question of, 764.
Cholecystitis and gallstone, diagnosis of, 783.
Cholera in Formosa, 382; in Korea, 553; in Siberia, to combat, 471; shock, and allied conditions, the balance of colloid and crystalloid in, 855.
Cholesteremia, the cycle of, 424.
Chondromata, 978.
Chorea of childhood, the, 930.
Christian Science psychosis, the, 1048.
Cinchophen, 426.
Cirrhosis, hepatic, the spleen and, 291; syphilitic, of the liver, 641.
Climacteric hypertension, the treatment of, 1027.
Clinic, the Minnesota rural, 1066.
Cold and the high cost of living, 78.
Colds, common, and grippe, 627; exposure and, 549.
Congelation, late thrombosis and gangrene following, 78.
Cook, Finley R.: cancer, a new technique in the treatment of, 1042.
Coolidge tube, the, in France, 895.
Cooties, an exterminator for, 510.
Copper, oligodynamic action of, 469.
Cornwall, E. E.: Some facts and principles of dietotherapy, 181.
Coronary arteries, some observations on thrombosis of the 521; sclerosis in Switzerland, 517.
Correction of erroneous statements in the Chicago Daily Tribune, 673.

Phthiriasis, diagnostic significance of, 1022; 1057.
Physical examination of applicants for industrial positions, 925; training system, Harvard adopts, 333.
Physician's salary, agreement to pay, 59.
Physiology, fathers of, 440.
Pityriasis rosea, 403.
Placenta, premature separation of the normally implanted, 611; previa, the treatment of certain cases of, by conservative measures, 610; the indications of manual detachment of the, when the latter is adherent, 77.
Plater, Felix, 996.
Pleural effusions, purulent, treatment of, 464; effusions, the value of an early diagnosis of, 744.
Pluriglandular syndrome, 772.
Pneumonia, a plea for the early administration of atropine in, 339; a reportable disease, 731; and empyema, surgical complications of, 742; and empyema: symptomatology and diagnosis; and its prophylaxis by bactirination, a new method for testing immunity by means of the whole blood, with especial reference to, 480; aspiration, fatal case of, caused by the ingestion of zinc stearate, 364; cases complicated with emphysema, report of a series of, 353; cause of, 157; factors influencing recovery and resolution in, with special reference to the chemistry of the exudate, 480; gripne, bacteriology of, 333; in the army camps, 710; influenza and, animal experiments with bacteria isolated from, 524; influenza and, further studies on prophylactic inoculation in, 217; influenzal, intravenous injection of foreign protein in, 32; influenzal, value of convalescent blood and serums in the treatment of, 217; its complications and sequelæ, the management of, 741; pericarditis as a complication of, based on three hundred necropsies, 82; sodium citrate in the treatment of, 811; treatment of, 12; types of, following influenza, 523; with delayed resolution, arsphenamin in, in syphilitic soldiers, 812.
Pneumonic consolidation, the whispered voice sound, an aid to the early diagnosis of, 412.
Pneumoperitoneum, further experiences with roentgen examination of the abdominal organs following oxygen inflation of the peritoneal cavity, with lantern slide demonstration, 946.
Pneumothorax, artificial, insufflation of carbonic acid in, 78; artificial, the effects of, 386.
Podalgia, see *Painful heel*.
Podiatry, the evolution of, 53.
Poliomyelitis cases, report on after-care of, 847; epidemic, serum treatment of, occurring in Dubuque, Iowa, during the summer of 1918, 972.
Polymyositis, acute, and trichinosis, 122.
Porter, William H.: absolute rest as a metabolic stimulant, 800.
Posology, need of reform in, 950.
Posture, the erect, 516.
Practice, general, the future of, 163; medical, the outlook of, 622.
Pregnancy, a case of repeated toxemias of, 279; acidosis in, 307; biological tests for, 766; glycosuria in, 606; the prognosis of albuminuria in, 423; toxicoses, nature of, 731.
Prenatal care, 859.
Preventable disease, some considerations of, 983.
Projectiles, intrathoracic, the delayed or late extraction of, by the method of Petit de la Villeon, 347; see also *foreign body;* war, extraction of, from the thorax, 190.
Prostate, absence of the, 413.
Prostatic obstructions, nonhypertrophic forms of, 1066.
Prostitution, a study of 168 cases of, 477.
Proteal therapy, a year of, 826; theory and practice of, 997.
Pseudoarthroses of the humerus consecutive to war wounds, 323.
Pseudoascites, 772.
Pseudo-Ménière's disease (angiospasm of the internal auditory artery), 496.
Pseudomyxoma peritonei, 713.
Psoriasis, a possible cause of, 1056; palmar and plantar, 243.
Psychiatry, elements of a pragmatic, 434.
Psychology: a plea and a prophecy, 434; as applied to medicine, Columbia University plans courses in, 932.
Psychoneuroses, sexual, as studied in a medical clinic, 745.
Psychosis, the Christian Science, 1048; the situation, 1.
Psychotherapy, the province of, 598.
Public health, industrial medical practice and sickness prevention as a factor in, 212; nurses, post-graduate course for, 471; service, U. S., division of industrial hygiene and medicine, the enlarged program of the, 213.
Puerperal period, the care of the bowels during the, 859.
Pulmonary excursion, the clinical study of, 80; suppuration, 441.
Pulse pressure in traumatic cerebral compression, 779.
Putti, Vittorio: National organization of rehabilitation of the disabled in Italy, 544.
Pyloric obstruction, hypertrophic, in infants, retrospect of fifteen years in the treatment of, 40.
Pylorospasm and pyloric stenosis, the atropine treatment of, 256.
Pyonephrosis, colon bacillus, in infancy, 257.
Pyramidon in febrile infectious processes, 168.
Pyretotherapy, 702.

Q

Quinine, the proportionate dose of, required to produce the same results in treating malaria in children of different ages, as in adults, 679.

R

Rabelais, medical neologisms of, 801.
Rabies, 514; on the nature of, and antirabic treatment, 677; the nature of, and the antirabic treatment, 708.
Radiotherapy: indications and results obtained when properly used, 388.

Radium in dermatology, 855; the use of in gynecology, 1067; the value of, in the treatment of bladder tumors, 1067; treatment of cancer, 765; treatment of uterine cancer, further observations on the, 712.
Ravdin, B. D.: the results of focal infections as seen in ophthalmology and otolaryngology, 975.
Raynaud's disease, 346.
Recklinghausen's disease, abortive forms of, 551.
Reconstruction in nervous and mental disease, 130; physical and mental rehabilitation of disabled soldiers of the United States Army, 131; plastic, salvage of the hand by early, 349; the medical aspects of, 129; the neurological aspects of, 125; the surgical aspects of, 124; the work of physical, as it concerns orthopedic surgery, 126.
Rectum, a case in which for over thirty-five years a woman defecated and urinated and for eleven years menstruated by the, 352.
Redfield, C. L.: The sticking points in development, 360.
Rehabilitation, medical social service in, 541; of the disabled in Italy, national organization of, 544; see *Reconstruction*; the industrial, of the cripple, 566; vocational, for those disabled in industry, 766.
Renal surgery, modern urological advances and their effects on, 1018.
Resection, submucous, of the nasal septum, a discussion of the, 775.
Respiratory diseases, communicable, prevention of, based upon observations in the army camps, 743.
Rest, absolute, as a metabolic stimulant, 800.
Resuscitation, theories on cardiac massage as a means of, 771.
Retina, curability of obliteration of the central artery of the, 1062.
Retroversion, a case of, with unusual symptoms, 885.
Rheumatism, chronic, thalassotherapy of, 705; muscular, eosinophilia of the blood in, 78; possible dietary causes of, 752.
Rheumatismal diseases, results of ablation of the tonsils in, 299.
Rickets, the antiquity of, 25; the causation and treatment of, 1028.
Robinson, Beverley: Notes about some cases of heart failure, 317; souvenirs of an old New York practitioner of medicine, 339.
Robinson, Edward Percy: does the cure of cancer depend upon oxidation of the tissues?, 9.
Roentgen ray as an aid to diagnosis in chest conditions, 739.

Sugar as a necessity, 786; treatment of tuberculosis, the, 927.
Suicide, false, 939.
Sunstroke "personal injury" within workmen's compensation act, 422.
Suppuration, metastatic perivenal, 806.
Surgeon, consulting, the Cavendish lecture on the rôle of, in war, 208; General, office of the, report of the work as seen in certain spheres of the, 1036.
Surgery, abdominal, under local anesthesia, 390; cosmetic, 295; hand, a plea for greater care in, 775; intranasal, without packing, 1064; pelvic, Trendelenburg ether anesthesia in, 390; preventive, as demonstrated by industrial practice, 212; renal, modern urological advances and their effects on, 1018; renal, the clinical value of preliminary study in, 311; the influence of the war on, 299; thoracic, personal experiences with, with the A. E. F., 303; war, phases of: bone transplants from the tibia to the lower jaw for loss of substance, 348; war, the influence of upon civil practice, 301; war, the probable influence of, on civilian life, 171; what would be the benefit

to the civilian surgeon of the experience gained by our military surgeons in the world war? 301.
Surgical barrage, 865; observations of war industrial activities at the Methodist Episcopal Hospital, Philadelphia, 778; Society, Swiss, 119.
Sutures, primary and secondary, 172.
Sympathetic nervous systems in disease, the Croonian lectures on the rôle of the, lecture III, 33; lecture IV, 76.
Symptoms, the importance of, 468.
Syndrome, a new familial, 670; effort, among drafted men at a recruit depot, observations on, 482; effort, and epinephrin, 669; effort, see *Asthenia, neurocirculatory;* the endocrinic fever, 885; Stokes-Adams, treatment of, 507.
Syphilis as a cause of delayed healing in the noninfected abdominal incision, 863; congenital, a study in a foundling institution to determine the existence of, 42; early diagnosis of, the dark field illumination method in, 234; late, of the central nervous system, the diagnosis of, 435; pulmonary, 744, 1067; spermatodiagnosis of, 908.

T

Teamwork, scientific, in the diagnosis and treatment of diseases of the eye, ear, nose and throat, 1064.
Teeth, the eruption of the, and the subsequent development of the jaw, 261.
Temperature disturbance as shown by some observations in the selective draft, the psychic factor as an element in, 81.
Testicle, placentomas and choriomas of the, 176.
Testicular grafts and surgical opotherapy, 847.
Tetanus, strychnine poisoning and, 433.
Thalassotherapy of chronic rheumatism, 705.
Therapeutics, materia medica and, the repudiation of, in modern medical teaching, 667; some general principles of, 814; the empirical origin of, 846; the present day teaching of, 678.
Thermometer, a, in the intestine, 464.
Thomas, Hugh Owen, memorial to, 336.
Thoracic fistula and chronic empyema; a nondeforming operation for their cure, 347; operations, the necessity for the application of differential air-pressure in, 617; viscera, roentgen diagnosis of diseases of the, 873.
Thornley, Roy A.: further evidence in support of the concentrated method of arsphenamine administration, 28.
Three-day fever, nervous system sequelae in, 394.
Thrombosis of the coronary arteries, some observations on, 521.
Thymus, a function of the internal secretion of, 621, 675; gland, a case of enlarged, 1036.
Thyroid disease, see *Goiter;* disturbance, the little signs of, 99; enlargement in adolescence, the relation of infected tonsils to, 737; function, clinical results with a method of testing, 722; gland, enlargement of the, in malaria, 1062; gland, experimental factors in the compensatory hypertrophy of the, 526; gland, the function of the, 526; gland, the operative treatment of simple enlargements and tumors of the, 209; hormone, chemical identification of the, 526; the iodides and the, 647.
Toes, hammer, 843.
Tonsillectomy, mechanical and physiological considerations in, 385; the advantages of gauze plugging after, 123.
Tonsils, infected, the relation of, to thyroid enlargement in adolescence, 737; results of ablation of the, in rheumatismal diseases, 299; simplified technique for local anesthesia of, 1065.
Trachoma hospital for Florida, 807.
Tracheotomy, tranquil, by injecting cocaine within the windpipe, 676, 813.
Transfusion, blood, an investigation of the end result in 124 cases of, 341; blood, as a therapeutic aid in subacute sepsis associated with war injuries, 588; blood, value of repeated small, in blood stream infections, 711; hemorrhage and, 171.
Treatment, contract for future, 23; course of—practising without license, 929.
Trench fever, 87, 414; nephritis, 237; nephritis at a British hospital in France, 527.
Trichinosis, acute polymyositis and, 122.
Tubercle bacilli, a convenient method for concentrating and isolating, 804.
Tuberculin, some clinical experiences in the treatment of children with, 39; therapy in children, some practical hints on, 455.
Tuberculomata of the spinal cord, 729.
Tuberculosis, a new cutaneous reaction in, 888; action of, on the psyche and character, 856; advocated division of, in United States Public Health Service, 26; anomalies of, in the Highlands of Colombia: a new diagnostic sign in incipient cases, 475; apical, and the orthograde posture, 265; board, an analysis of the examination of over 100,000 men examined at Camp Lewis, Washington, by the, and of 25,000 soldiers discharged from service, 941; chronic pulmonary, errors in the diagnosis of, 83; chronic pulmonary, the diagnosis of, 207; chronic pulmonary, the humoral reactions of, 1029; clinic state, a success, 509; concerning, 1020; diagnosis of, from the standpoint of the radiographer, 263; diagnosis of, motion pictures in the, 262; early diagnosis of, from the social viewpoint, 253; film on diagnosis of, being shown in New York State, 509; hypertension in, 887; in French army, 161; in New York herds, 202; in the army, 642; in the Balkans, 703; influenza and, 123; intestinal, the early diagnosis of, 524; manifest, hookworm and, 1066; modern treatment of, 1015; problem, the, after the world war, 135; problem, the army, as seen in Massachusetts, 491; pulmonary, a few derogatory remarks concerning the inhalation treatment in, 210; pulmonary, points of differential diagnostic value in pulmonary abscess, bronchiectasis, and, with an explanation of the difference in auscultatory findings, 990; pulmonary, some lessons of the war in, 989; pulmonary, the present status of therapeutic pneumothorax in, 743; pulmonary, therapeutic problems in, with disturbance of the cardiovascular system, 584; regimen, the, 278; rest in, 608; state care of tuberculous men, 202; the end results of employment of ex-patients in sanatoria for, 942; the epidemiology of, 168; the necessity of accuracy in the diagnosis of, 836; the sugar treatment of, 927; the treatment of, in an army hospital, 940; the treatment of, in returned Canadian troops, 1036; ulcerating pulmonary, in infants, the general symptoms of, 886; patients, diurnal variation in body-weight in, 813.
Tuberculous soldiers, 554.
Tudor, Thomas J.: prophylaxis of the sequelae of, 101.
Tuffier, Th.: treatment of purulent pleural effusions, 464.
Tumor, fibroid, of the uterus, the origin of the intrapelvic treatment of the stump after supravaginal hysterectomy for, 609; hysterical, 885; uterine, a unique diffuse, really an adenomyoma with stroma but no glands; menstruation, after complete hysterectomy, due to uterine mucosa in the remaining ovary, 610; camphorated oil, 812; of the breast, based on a study of seventy-seven cases personally observed, 864; fibroid, of the uterus, toxic effect of, 609.
Typhoid fever, changes in the cerebellum in, 36; spondylitis, the evolution of, 1020; the specific treatment of, 982; spine, 122.
Typhus, energetic action needed to control, 714; fever, bacteriological findings in, 77; fever, experimental studies on, 78; fever, virus of, 978; recent additions to our knowledge of, 730; serum, 1023; the louse and, 805.

U

Ulcer, chronic, of the and duodenum, the modern medical treatment of, with special reference to the Sippy method, 867; duodenal and gastric, a new operation for, 391, 431; duodenal, the anatomical evolution of, 379; gastric, adhesive perigastritis in, 509; gastric and duodenal, life expectancy of patients following operations for, 351; gastric and duodenal, surgery of, in continental Europe, 244; gastric and duodenal, the efficiency of surgical treatment in the bleeding type of, 391; peptic, operative treatment of, 350; peptic, results of duodenal alimentation in, 95; perforated gastric, a case of, with abscess formation; perforation through the lung with spontaneous recovery, 478.
Unrest, the emotional, its causes and treatment, 787, 822.
Urethra, inflammation of the bulb of, 289.
Urinary affections, simulation of, by soldiers, 381.
Uterus, cancer of the, age distribution and age incidence in 500 cases of, 711; semeiotic value of curettage in malignancy of the, 1028.

V

Vaccination, an early publication on, 438; by subcutaneous injection, 515.
Vaccine as a prophylactic against influenza, and local reaction as a guide to immunity, 624; treatment of arthritis, rheumatism, and neuritis, some causes of failure in the, 813.
Vaginal discharge, the treatment of, 862.
Vanderhoof, Douglas: Therapeutics and gastrointestinal disorders, 487.
Vegetables, canned, the antiscorbutic and growth-promoting value of, 556.
Vena cava, inferior, obliteration of the, 378.
Venereal diseases, an intensive study of the prophylaxis and treatment of, 427; control, pioneering in, 858; in Cuba, prophylaxis of, 388; in extra-cantonment zones, the detention and treatment of infected women as a measure of control of, 858; lectures on, 511; Pennsylvania's campaign against, 741; prevention, 512; symposium on, 858; the value of detention as a reconstructive measure, 858; the work of the detention home for women in the management of, 858; problems of the war, 60, 104; prophylaxis, 700.
Ventricular (cardiac) excitatory process, the significance of prolongation of the, 524.
Version, my experience with cases of, during the past year, September, 1918, to September, 1919, 861.
Vertigo, voltaic, and galvanic nystagmus, the diagnotic value of, in diseases of the middle ear and labyrinth, 1055.
Vestibulor disturbance, auditory, lesions of the fifth cranial nerve in connection with, 1064.
Vincent's disease, 1065.
Virus, filterable, 469.
Viscera, abdominal, acute perforations of, 66; thoracic, roentgen diagnosis of diseases of the, 873.
Visceral disease, symptoms of, 896.
Visceroptosis, rational surgery of, 392; the treatment of, 1064.
Vital statistics in Havana, 748.
Vivisection in Great Britain in 1918, 555.
Volkmann's disease in the lower extremity, 146.
Voorhees, Irving Wilson: the respiratory tract as a portal of entry in infectious disease, 956.
Vulgus vult decifi, 176.
Vulvitis, chronic, 425.

W

Waiver of warranty by medical examiner, 422.
Walker, Dr. Mary, a Spanish appreciation of the late, 748.
War, a few surgical lessons of the, 984; an address on some applications of experience gained by the, to the problems of civil medical practice, 557; cancer and the, 113; chest wounds in, see *Chest;* child welfare work abroad during the, 258; conditions, nutrition of the German people under, 78; consulting surgeon in, 208; cost in man power, 600; dermatoses of the, 280; emergency measures become permanent, 161; fractures, 174; fractures, statistical summary of, 174; injuries, see *Injuries;* lesson as applied to civil

practice, 341; medical and surgical lessons of the, 16, 591, 628; nephritis, see *Nephritis;* neuroses as observed in army neurological hospitals at the front, 297; neuroses, cardiac phase of, 129; problems, 172; projectiles, see *Projectiles;* recent world, what would be the benefit to the civilian surgeon of the experience gained by our military surgeons in the, 301; risk insurance act, an important provision of the, 671; some lessons from the, for abdominal surgeons and others, 864; some lessons of the, in pulmonary tuberculosis, 989; some medical impressions of the, 569; surgery, the influence of, upon civil practice, 301; surgery, the probable influence of, on civilian life, 171; surgery, see *Surgery;* the influence of the, on surgery, 299; the medical profession in the; its sacrifices and compensations; humanity's gains, 1066; the physiology of alimentation; results obtained during the, 123; the physiology of alimentation during the, 168; venereal problems of, 60; venereal problems of, 104; wounds, see *Wounds.*
